ANNOUNCEMENT

AVAILABLE NOW

Special Facilities Exclusive to B.M.A. members, I.M.A. Subscribers and B.M.S.A. members

You will be anxious to join the Facilities Division of Independent Medical Services Ltd. when you know the value of the many services it can offer.

This symbol represents
a new service for
YOU

Facilities Division

This symbol represents
a new service for
YOUR FAMILY

These services provide at highly advantageous terms the widest range of goods, car purchase, car hire, hire purchase and credit facilities, as well as other attractive offers. The scheme is available only to B.M.A. members, subscribers to the funds of I.M.S. and B.M.S.A. members.

Write now for details to :

Vasogen Silicone —for skin protection in cases of bedsores, napkin rash cracked skin, itching and other skin disorders

Vasogen Silicone has high water repellent properties and protects the skin from irritants induced or aggravated by contact with aqueous liquids, body fluids and exudations. It is effective also in the treatment of sore buttocks, excoriation, plaster sores, maceration, some conditions of eczema and can be used after colostomy. Vasogen Silicone is easy to apply and is almost invisible on the skin. It provides an acceptable protective barrier that is maintained effectively for lengthy periods.

FORMULA

Dimethyl Silicone Fluid B.P.C.	20.0%
Zinc Oxide B.P.	7.5%
Calamine B.P.	1.5%
in an emulsified base

Three Unique Anticholinergics

with exceptional therapeutic characteristics

PIPTAL

(Pipenzolate methobromide)

For Peptic Ulcer

Piptal decreases acid secretion, suppresses abnormal gastric motility and relieves the pain of peptic ulcer.

It is unusually well-tolerated, even when administered over long periods.

DACTIL

(Piperidolate hydrochloride)

For Gastro-duodenal Spasm

Dactil selectively relieves pain due to upper gastro-intestinal spasm usually within ten minutes. Indications include abdominal cramps as in gastro-duodenal spasm, as well as biliary spasm, hiatus hernia, cardiospasm, pylorospasm, post-gastrectomy syndrome and regional ileitis.

CANTIL

(Mepenzolate bromide)

For the Colon

Cantil effectively relieves pain due to colonic spasm in irritable colon, spastic colitis and diverticulitis. It counteracts colonic hypermotility in acute and chronic non-specific diarrhoeas, mucous colitis and ulcerative colitis.

SIDE EFFECTS have only rarely been observed. The selective actions of all three products—*fully supported by extensive clinical trials*—have been found to provide a high degree of therapeutic efficacy with almost complete freedom from the side effects commonly attributable to anticholinergic drugs.

CONTRA-INDICATIONS—Piptal, Dactil and Cantil are contra-indicated in glaucoma and should be used with caution in prostatic hypertrophy.

Indispensables

Certain things are *basic* . . . The books, for instance. You may not take them down every day, but you *know* them. Sound, fundamental.

You know Aspellin, too. A really effective, economical treatment for rheumatic conditions and muscular trauma—a spirit-based liniment containing Acid Acetylsalicylic to relieve symptomatic pain *rapidly*, and Methyl Salicylate, with Menthol and Camphor, to reduce inflammation and muscle tension.

Rheumatism sufferers can only obtain Aspellin if you prescribe it. Aspellin is *only* obtainable on prescription. Cost: 10½d. per oz.

ASPELLIN—indicated in the treatment of acute rheumatic conditions, sciatica, lumbago, fibrositis, muscular trauma.

Professional literature and samples from: Radiol Chemicals Ltd., Stepfield, Witham, Essex. Tel. Witham 2538

A Spencer Support for Visceroptosis

Spencer Support closed. The concealed inner abdominal section is adjustable at several different points from the outside of the support.

RELIEVES SYMPTOMS,

PROMOTES A SENSE OF WELL-BEING

It has been found that practically every ptotic patient experienced relief of symptoms, increased energy and sense of well-being following application of proper support.

The doctor can rely upon Spencer for *proper support* because each Spencer is individually designed, cut, and made for each patient from detailed measurements and a complete description of that patient's body and posture.

With a Spencer, the co-relation of abdominal and back support induces correct posture, modifies an unfavourable tilt. Ptosed organs are lifted to normal position to improve circulation. Better digestion, elimination, respiration often result.

(Right)
Spencer Support shown open revealing inner abdominal section.

Three Unique Anticholinergics

with exceptional therapeutic characteristics

PIPTAL

(Pipenzolate methobromide)

For Peptic Ulcer

Piptal decreases acid secretion, suppresses abnormal gastric motility and relieves the pain of peptic ulcer.

It is unusually well-tolerated, even when administered over long periods.

DACTIL

(Piperidolate hydrochloride)

For Gastro-duodenal Spasm

Dactil selectively relieves pain due to upper gastro-intestinal spasm usually within ten minutes. Indications include abdominal cramps as in gastro-duodenal spasm, as well as biliary spasm, hiatus hernia, cardiospasm, pylorospasm, post-gastrectomy syndrome and regional ileitis.

CANTIL

(Mepenzolate bromide)

For the Colon

Cantil effectively relieves pain due to colonic spasm in irritable colon, spastic colitis and diverticulitis. It counteracts colonic hypermotility in acute and chronic non-specific diarrhoeas, mucous colitis and ulcerative colitis.

SIDE EFFECTS have only rarely been observed. The selective actions of all three products—*fully supported by extensive clinical trials*—have been found to provide a high degree of therapeutic efficacy with almost complete freedom from the side effects commonly attributable to anticholinergic drugs.

CONTRA-INDICATIONS—Piptal, Dactil and Cantil are contra-indicated in glaucoma and should be used with caution in prostatic hypertrophy.

“IS THERE AN ALTERNATIVE?”

The N.H.S. is ailing. Must it stay that way?

Recently the *B.M.J.* has examined alternative ways of finding money and administering the service. What about a corporation? Or decentralization? Or a lottery? Or private insurance? These and other possibilities have been considered by experts in economics and related fields. All the articles have now been reprinted in booklet form, with a medical summing up by Sir Robert Aitken, Vice-chancellor of the University of Birmingham. Anyone with an interest in the National Health Service must read this book.

Price 7s. (U.S.A. \$1.00) postage extra

*This 74 page B.M.J. paperback Is there an Alternative?
can be ordered through your local bookseller or direct from*

INDEPENDENT MEDICAL SERVICES

THANKS THE 14,000 DOCTORS WHO HAVE APPLIED FOR MEMBERSHIP OF THE FACILITIES DIVISION

Due to this overwhelming response and some printing difficulties there will be a short delay in some cases before applicants receive their membership cards and catalogues. In the meantime, should you require goods or services, or have specific enquiries,

Write to us at:
Facilities Division,
Independent Medical Services Ltd.,
Tavistock House South,
Tavistock Square,
London, W.C.1.

FACILITIES DIVISION

or:
telephone us at
01-387 8261

when your request will be given every attention.

THE HUNGARIAN PHARMACOLOGICAL SOCIETY

will hold the

Fifth Hungarian Conference on Therapy and Pharmacological Research in Budapest, from 1st October to 5th October, 1968.

The Organizing Committee will accept all papers dealing with new pharmacological and clinicopharmacological methods and new pharmaca.

Reports concerned with the following fields are especially welcomed.

Chemotherapeutics and substances acting on:

the central nervous system,
the circulation,
metabolism.

INFORMATION: J. Purman, General Secretary of the
Congress, Budapest 502 · P.O.B. 18 · Hungary

ANTIBIOTICS AND THE INTESTINAL FLORA

Treatment with broad spectrum antibiotics suppresses the normal flora, which may be replaced by abnormal resistant organisms causing diarrhoea.

This change can be prevented or reversed by the implantation of *Lactobacillus acidophilus* which has been rendered antibiotic-resistant, and is thus able to multiply freely under these abnormal conditions. The products of growth of the organism are inimical to that of many other bacteria^{1,2} and thus contribute to its rapid preponderance over other species.

Oral treatment with antibiotic-resistant *L. acidophilus* in the form of ENPAC has been shown to eliminate *Candida* from the faeces of infants with antibiotic-induced diarrhoea, with relief of symptoms succeeded by rapid gain in weight^{3,4} and greatly to reduce the numbers of staphylococci in the faeces of patients treated with tetracyclines.⁵

LEPETIT S.p.A. MILAN - ITALY

ANTIBIOTICS, CORTICOSTEROIDS, PSYCHO-DRUGS, VITAMINS

During the past 50 years, modern pharmacology has given medicine more drugs than in the past 5000 years.

This is the result of scientific research, the yardstick used to measure the importance of a pharmaceutical company. The activity of Lepetit research-workers, starting way back in 1903 with the preparation of Almagine (tetramethylethoxylin), which was patented in the United States and other countries, is confirmed by over 1,700 patents granted throughout the world since 1945, by 2,800 pending applications and by over 800 published papers.

In recent years, the Lepetit Research Laboratories discovered and developed a completely new family of natural and semi-synthetic antibiotics, the rifamycins, including rifamycin SV (Rifocin®), rifamide (Rifocin® M) and rifampicin, the first orally active rifamycin.

Indispensables

Certain things are *basic* . . . The books, for instance. You may not take them down every day, but you *know* them. Sound, fundamental.

You know Aspellin, too. A really effective, economical treatment for rheumatic conditions and muscular trauma—a spirit-based liniment containing Acid Acetylsalicylic to relieve symptomatic pain *rapidly*, and Methyl Salicylate, with Menthol and Camphor, to reduce inflammation and muscle tension.

Rheumatism sufferers can only obtain Aspellin if you prescribe it. Aspellin is *only* obtainable on prescription. Cost: 10½d. per oz.

ASPELLIN—indicated in the treatment of acute rheumatic conditions, sciatica, lumbago, fibrositis, muscular trauma.

Professional literature and samples from: Radiol Chemicals Ltd., Stepfield, Witham, Essex. Tel. Witham 2538

SPECIAL CHRISTMAS OFFER TO IMS MEMBERS

CASE A—(Red Burgundy)

12 bottles Volnay 1962, Moreau-Fontaine—162/- per case, reduced from 174/- per case.

Tremonil

WANDER

the steadying
influence in
Parkinsonian
tremor

Tremonil is a valuable drug for use in all types of Parkinsonism, whether naturally occurring or drug-induced. It is particularly effective against tremor, and may be used concurrently with other drugs having as their main action an effect on rigidity.

BRITISH HEART FOUNDATION APPEAL

CORONARY CAN KILL

IN THE PRIME OF LIFE

ALL DOCTORS know how often and at how young an age Coronary Thrombosis and other heart diseases can kill.

BUT do their patients know that the **BRITISH HEART FOUNDATION** was founded to finance research into these dread diseases?

And do they know that they can help—

- * BY MAKING A DONATION
- * TAKING UP MEMBERSHIP
- * REMEMBERING THE BRITISH HEART FOUNDATION IN THEIR WILL
- * MAKING AN 'IN MEMORIAM' GIFT IN LIEU OF FLOWERS?

**GIVE
WHOLEHEARTEDLY**

57 Gloucester Place, London W1

ANTIBIOTICS AND THE INTESTINAL FLORA

Treatment with broad spectrum antibiotics suppresses the normal flora, which may be replaced by abnormal resistant organisms causing diarrhoea.

This change can be prevented or reversed by the implantation of *Lactobacillus acidophilus* which has been rendered antibiotic-resistant, and is thus able to multiply freely under these abnormal conditions. The products of growth of the organism are inimical to that of many other bacteria^{1,2} and thus contribute to its rapid preponderance over other species.

Oral treatment with antibiotic-resistant *L. acidophilus* in the form of ENPAC has been shown to eliminate *Candida* from the faeces of infants with antibiotic-induced diarrhoea, with relief of symptoms succeeded by rapid gain in weight^{3,4} and greatly to reduce the numbers of staphylococci in the faeces of patients treated with tetracyclines.⁵

"IS THERE AN ALTERNATIVE?"

*"The British Medical Journal has produced a series of articles, now collected in book form under the title *Is There An Alternative?* with which many of you will be familiar. The object of these essays—ranging widely as they do from what one might almost call pure organisation theory to the possibility of a sweepstake to finance hospital services—seems to have been to provoke people to think about the range of possible alternative structures. If I may say so, this seems altogether helpful: there is not one, there are many possible ways of restructuring the Health Service."*

CHILD CARE

This book is the second to be published from a series of articles that have appeared in the "Current Practice" section of the *British Medical Journal*. It gives practical up-to-date advice on problems faced by general practitioners. The articles that make up the book cover the period from infancy to adolescence, and in their scope cover child-care in the broadest sense, with sections on normal development, adoption, puberty, and behaviour disorders as well as the diagnosis and management of childhood diseases. The authors are consultant paediatricians or leading authorities in their fields, but the emphasis throughout has been on a practical approach. It is hoped that the book will be a useful guide for all family doctors.

ALCOHOL & ROAD TRAFFIC

PROCEEDINGS OF THE
THIRD INTERNATIONAL CONFERENCE
ON ALCOHOL AND ROAD TRAFFIC
HELD UNDER THE AUSPICES OF
THE *BRITISH MEDICAL ASSOCIATION* IN
SEPTEMBER 1962

AN IMPORTANT REFERENCE BOOK for police surgeons, lawyers, forensic scientists, police officers, criminologists, doctors, sociologists, psychologists, insurance offices, analytical chemists and others whose work brings them into contact with the problem of alcohol and road traffic.

In September 1962, the world's leading authorities met together in London to discuss problems of alcohol and road traffic. The 56 papers which were presented at this conference, the subsequent discussions, and the reports of nine special working parties set up to discuss particular issues, have been collected together in these proceedings to form the most comprehensive and authoritative statement available on this important and topical subject.

The proceedings contain the most up-to-date information on the relation of alcohol, tranquillizers and other drugs to road accidents, the role of alcoholism, the most recent chemical methods of detection including breath analysis, A.D.H. and gas chromatography, police procedure with drinking drivers, and presentation of evidence in courts of law.

Sainsbury Report

Last week the report of the Sainsbury Committee¹ was published as a Command Paper. Appointed in May 1965 by the Minister of Health and the Secretary of State for Scotland, the Committee was asked to look into the relationship of the pharmaceutical industry in Great Britain with the National Health Service. In its inquiries it was to have regard to the structure of the industry, to the commercial policies of the firms comprising it, to pricing and sales promotion practices, to the effects of patents, and to the relevance and value of research. And it was asked to make recommendations. As well as taking evidence from interested associations and professional bodies (including the Royal Colleges and the B.M.A.), Lord Sainsbury and his colleagues initiated several inquiries of their own. They obtained from the pharmaceutical industry replies to a financial questionnaire; they visited factories; at their request the Government Social Survey carried out a study of the sources of information on drugs of 500 general practitioners and how these related to their prescribing habits; and they tested the degree of concordance between two expert panels, one in London and the other in Edinburgh, who were asked independently to categorize on the basis of therapeutic effectiveness some 2,657 proprietary preparations listed in the Monthly Index of Medical Specialties (M.I.M.S.) for December 1965. The result of this searching investigation has been in the hands of the appointing Ministers for some little time.

By far the largest buyer of drugs in this country is the State. That a customer in such a dominant position should find it necessary to inquire into the business methods of those it shops with gives an impression of seeking a tool to impose greater control over the producer than the normal workings of the market—weighted in this case in the customer's favour—have made possible or warranted. The medical profession, which has reason to be grateful for the drug manufacturers' contribution to advances in medicine, will therefore welcome the Committee's acknowledgement, though somewhat grudgingly made, that the industry "cannot be said to have failed to provide the people of this country with many medicines of great value." On the questions of prices and profits, medical men are not as competent to comment as a body with such an eminent business man at its head as Lord Sainsbury. But the majority of doctors, as indeed of the public, will be glad that nationalization as a panacea for the problems of the industry is rejected.

If—as the Committee states—the industry in many ways has "admirably served the public interest," it must also be agreed that the importance of drugs and medicines for human welfare imposes a special responsibility on both the industry and the Health Departments. The Committee gives short shrift to those who argue that most research which leads to new medical products is done in the universities and that the pharmaceutical industry lives by exploiting other people's inventions. In fact the industry is far from being wholly or even largely dependent on the

universities for basic research, and the major part it has played in the great advances in therapeutics during the past few decades is recognized by the Committee.

Some 55 to 60 firms in Britain account for over nine-tenths of the total value of sales of "prescription medicines." Many of these firms are foreign owned. In 1966 nearly half (by value) of the medical specialty products (ethical proprietary preparations) prescribed under the N.H.S. came from U.S.-owned companies in Britain, 27% from British companies, 14% from Swiss companies, and 10% from other European-owned companies. This picture omits the export performance of these firms, which is impressive—an increase of over 50% between 1961 and 1965, with "by far the largest contribution" by British-owned firms. In 1965-6 the cost of medicines, dressings, and appliances in the Hospital Services had risen threefold over 16 years to £24.6m., while in the General Medical and Pharmaceutical Services there had been a fourfold rise to £148.9m. Of N.H.S. expenditure on medicines, dressings, and appliances 90% is for medical specialties, so their importance for this inquiry is clear.

After a thorough consideration of the many factors relevant to a fair level of profit—the size of the risk, need for incentive, patent monopoly, product competition, and so on—the Committee concluded that the actual level of profits was in some cases much higher than could be considered reasonable, and that the Ministry's voluntary price regulations schemes had serious weaknesses. The Committee proposes new pricing arrangements, which include the statutory provision of an audited financial return by companies supplying N.H.S. medicines and a standard cost return for new drugs and existing ones with N.H.S. sales exceeding £250,000 annually. Its recommendation for the appointment of a separate Economic Development Committee to watch over the development of the industry comes rather oddly in relation to an industry which has been so successful. The Committee also wants new pharmaceutical products to be marketed only under an approved name, and not by brand name. This last proposal should help to make clinical therapeutics easier and perhaps more rational. Certainly it goes in a direction favoured by much of the medical evidence given to the Committee, including that of the B.M.A.

In many ways the most far reaching of the Committee's recommendations is that for the Medicines Commission. It is not without significance that the Government issued its White Paper² on its own proposals for legislation on drugs and medicines just a fortnight in advance of the Sainsbury report. As we noted at the time,³ the Medicines Commission the Government wants would have as its first task the giving of advice to the Ministers of Health and Agriculture, and its members would be appointed (after consultation with "appropriate organizations") by the Ministers themselves. It would in fact be an extension of the Government machine. The Sainsbury Committee, on the other hand, recommends an independent Medicines Commission. "We consider," the report states, "that a new body is required. It should have an independent constitution and be plainly seen to be independent. It is our aim that except for its necessary dependence upon the Government for the allocation of funds, it should be free from direct control by the Ministry of the day." The Commission, which would have statutory powers,

would advise the Health Departments on the licensing ultimately of all prescription medicines sold in Britain. It would perform the duties now carried out by the Committee on Safety of Drugs (Dunlop Committee) and the Standing Joint Committee on the Classification of Proprietary Preparations (Macgregor Committee), and take over from the G.M.C. its pharmacopoeial responsibilities. It would also be the statutory body to which the Government could turn for advice on all questions involving medicines.

The Committee believes that the Commission should become in due course the accepted source of information on all matters concerning the use of medicines. It thinks it unsatisfactory that so large a part of the information on medicines available to doctors should come from the industry selling them, and equally unsatisfactory that the profession should be under the impression that much of the other information represents only the views of the Health Departments and is activated wholly or mainly by a desire to save money. "The profession would in our view have much greater confidence in such information were it given by the independent, professionally staffed Commission." It is envisaged that the Commission would ensure that all information tendered to doctors by pharmaceutical companies is "impartially presented, complete, and as accurate as possible."

It is to be doubted whether the Medicines Commission would "from its very constitution" gain the confidence of the profession, as the Committee thinks that it would. The virtues of the Commission's independent status are likely to be dimmed in doctors' eyes when they contemplate its all-embracing powers and the bureaucratic machine that will be needed to operate them. Its responsibilities would be so onerous that they might prove unmanageable. And in contrast to its remit "to examine the relationship of the pharmaceutical industry in Great Britain with the National Health Service" the Committee's proposals for the Medicines Commission cover the whole of medical practice, not only the N.H.S. In this context it is difficult to agree with the Committee's thesis that the Commission should in due course become the accepted source of information on all matters concerning the use of medicines. There is at present in the medical journals a widely accepted source of factual information on current therapeutics which has played no small part in bringing together the reputable products of the pharmaceutical industry and the patients that benefit from them. It would have been easier to see the wisdom of some of the Sainsbury Committee's proposals had it been readier to recognize some of the virtues of the existing system.

Broken Hearts

William Heberden's mortality tables¹ for the City of London listed "griefs" as a cause of death, but it is doubtful if such a diagnosis would be accepted today. Deaths following bereavement used to be attributed to a "broken heart," and in 1835 Benjamin Rush² described rupture of the auricles and ventricles as the cause of death in such cases. The possibility that this may be something more than a medical myth is suggested by the recent work of C. M. Parkes and B. Benjamin.³ These workers showed that the increase in mortality rate among London widowers during the first six months of bereavement is largely attributable to deaths from coronary thrombosis and arteriosclerotic heart disease.

¹ *Report of the Committee of Enquiry into the Relationship of the Pharmaceutical Industry with the National Health Service, 1965-67, 1967, Cmd. 3410. H.M.S.O.*

² *Forthcoming Legislation on the Safety, Quality, and Description of Drugs and Medicines, 1967. Cmd. 3395. H.M.S.O.*

³ *Brit. med. J.*, 1967, 3, 689.

A paper by W. D. Rees and S. G. Lutkins printed at page 13 of this week's *B.M.J.* describes the effect of a death in the family on the death-rate of the surviving members. Their most striking finding in the semi-rural Welsh community which they studied is a mortality rate among newly bereaved family members six times greater than the mortality rate among non-bereaved control families. They confirm the findings of several other studies that there is an increase in mortality rates among widows and widowers and that this increase is most marked during the first year of bereavement.

Granted that there is an association between bereavement and mortality, how can this be explained? The evidence so far reported does not allow us to do more than guess. Does bereavement influence the incidence of disease or simply increase the mortality rate among those already affected? Is it the psychological state of grief which alters physiological processes in a pathological manner? Or does grief have secondary effects on diet, smoking habits, and alcohol intake, which are themselves pathological in their effects? Further research must answer these questions, but in the meantime doctors should ask themselves whether there is anything which they should be doing to mitigate the effects of bereavement.

In public health terms the relatives of dying patients are a high-risk group akin to the relatives of patients with tuberculosis. Rees and Lutkins's figures suggest that young and middle-aged men who lose wives from an illness which causes them to die away from home are particularly at risk. Recent work in Britain and the United States seems to indicate that major bereavements influence physical and mental health in many ways and that bereaved people commonly seek help from their medical practitioners. The clergyman, whose traditional role includes the succouring of the bereaved, has now in Britain been largely replaced by the general practitioner, the professional man to whom the bereaved will turn most readily. It is unfortunate that medical education does little to prepare doctors for this role.

Much is known about the form and nature of grief. Grief is the psychological process which cushions the impact of disaster and enables a bereaved person gradually to work towards an acceptance of what has happened. It is a mixture of pining and resignation, searching and apathy, denial and acceptance; small wonder that some are unable to cope effectively with this conflict. Pathological forms of grief have been recognized since E. Lindemann's classic account⁴ of grief among the relatives of those who died in the Coconut Grove fire. More recently papers by C. Anderson⁵ and Parkes⁶ have enabled the classification of bereavement reactions to be carried out. A common form is the "chronic grief" syndrome epitomized by Queen Victoria. Here, intense grief, instead of resolving, becomes habitual, and mourning persists. Another form may occur among persons who defend themselves so vigorously against the pain of grief that they "feel nothing" for months after bereavement. Thereafter they tend to break down with a particularly severe reaction. Identification symptoms (hypochondriacal symptoms resembling those suffered by the dead person during his terminal illness), panic attacks, insomnia, and headaches are

all likely to bring the bereaved person* into the care of a physician.

At present too little is known about the factors which decide who will break down and who will emerge from the stress of grief stronger and wiser. Personality factors, social isolation, age (old people withstand bereavement better than young), and the nature and magnitude of the loss itself all seem to be important factors. When the bereaved person is supported by a united and affectionate family, when there is something left to live for, when the person has been adequately prepared for the loss, and when it can be fitted into a secure religious or philosophical attitude to life and death there will seldom be much need for professional help. When, however, the bereaved person is left alone in a world which is seen as hostile and insecure, when the future is black and the loss has not been prepared for, help may be needed.

What can doctors offer? A willing ear, tolerant of confusion and anger, and a knowledge of community resources are probably more important than tonics and sedatives. In addition, the Cruse Clubs Counselling Service for Widows,⁷ the citizens' advice bureaux, the local church, mental welfare officers, social workers, and voluntary organizations of all kinds are available in many areas. There is little doubt that time spent in helping patients to prepare for and cope with the disasters in their lives will improve community mental health and may even reduce the post-bereavement mortality rate.

Prevention of Rhesus Haemolytic Disease

Rhesus haemolytic disease of infants takes several forms. In the mildest cases the infant is merely jaundiced and this soon disappears; in severer cases there is actual haemolytic anaemia, and this, if untreated, can be fatal; the disease can so affect the foetus that it will die in utero and be stillborn; and the hyperbilirubinaemia can affect the brain, producing the condition of kernicterus, which causes mental abnormality. The anaemia has been successfully treated by the method of exchange transfusion, and recently this procedure has been carried out before birth by the technique of intrauterine transfusion.¹ Early induction of labour has reduced the number of stillbirths, especially since the introduction of a method of using samples of amniotic fluid to give warning of dangerous concentrations of bilirubin.^{2,3} Nevertheless, it would be far more satisfactory to prevent this disease occurring at all. For the past nine years a group of doctors at Liverpool have been working on this problem, and they have now reached the point where the possibility of successful protection against rhesus haemolytic disease has been demonstrated and practical methods for making this protection available can be discussed. In his Lumleian lecture to the Royal College of Physicians printed on page 7 of this issue, Professor C. A. Clarke reviews the inception and development of this work in Liverpool and the information now available from other centres. It is an impressive story.

We now know that the cause of the disease is the development in the mother's blood of anti-Rh antibodies which pass the placenta and destroy the infant's red cells. The development of these antibodies in the mother's plasma is

stimulated by the passage of Rh-positive red cells from the infant to the mother across the placenta during labour. Another possible cause is the previous transfusion of the mother before her pregnancy with Rh-positive blood, but such an event is rare today. It follows that it is the second and subsequent children that are at risk, and since the stimulation may produce increasing levels of Rh-antibody production the risk is greater for each succeeding child. But in practice only a small proportion of the children at risk actually develop signs of rhesus haemolytic disease. There are at least two reasons for this. Different individuals react differently to similar antigenic stimuli, so in some families the second child is affected, whereas in others of three or sometimes more children no cases have occurred. Secondly, we know that if mother and child have different ABO blood groups, Rh immunization rarely occurs, presumably because the incompatible red blood cells from the child are destroyed in the mother's blood before they can do any damage.

It was this protection afforded by ABO group incompatibility that suggested a possible line of approach to Professor Clarke and his colleagues. If a potent anti-Rh serum was available, would it protect mothers against Rh immunization and their children against risk of rhesus haemolytic disease? When Rh-positive red blood cells were given to Rh-negative male volunteers they produced Rh antibody in their plasma. It was found that antibody formation could be prevented by giving a potent anti-Rh (anti-D) plasma, provided the "incomplete" (albumin) antibody was used. The next step was to give to women at risk, within 48 hours of delivery, 5 ml. of gammaglobulin containing incomplete anti-D of suitable activity. The trial was limited to primiparous women who were found to have foetal red cells present in their own blood after delivery—a group known to be at risk. Alternate patients were given the serum. After six months none of the 78 treated women had developed immune antibody, whereas 19 of the 78 controls had done so. Results up to date from various centres collected by Clarke show that out of 559 control cases 75 (13%) had become immunized six months after labour, whereas out of 628 protected by anti-D gammaglobulin none was immunized—a result which Clarke calls "almost alarmingly successful." Further results have shown that the protective effect will persist through a further pregnancy when the foetus is Rh-positive and ABO compatible; combined results show that out of 66 women immunized during and after pregnancy none produced antibodies in the subsequent pregnancy, whereas out of 63 control cases 15 (24%) produced antibodies.

There is thus clear evidence that women at risk can be protected against Rh-immunization and their children against rhesus haemolytic disease. Professor Clarke deals then with two further questions that arise. What are the risks of the procedures? Can enough anti-D gammaglobulin be obtained? The risk to the mother is trivial; only minor local reactions have occurred and the risk of serum jaundice can be eliminated by appropriate methods of preparing the gammaglobulin. The male volunteer who is injected with Rh-positive blood risks being infected by the virus of homologous serum-jaundice. The risk can be minimized but not eliminated by following W.H.O. recommendations. A better way, proposed by Clarke, is to use a small number of donors made hyperimmune by small repeated injections of sensitizing antigen and to obtain plasma by plasmapheresis—that is, to take off plasma and return the red cells to the donor. Put against the possibility of eliminating unnecessary stillbirths, some

cases of mental deficiency, and the who exchange transfusion, Clarke considers that acceptable, though others may not agree.

To get enough protective anti-D gammaglobulin calculates that for every million of the population 15 immunized donors, willing to give 500 ml. of plasma once a month, would be needed. The organization of the immunization of donors, the collection of plasma, and the preparation of protective antibody will therefore require quite a large staff with necessary equipment, but it could also be found by proper expansion of the present national blood transfusion centres.

Metronidazole and Syphilis

Metronidazole (Flagyl) was introduced to therapeutics in 1959 after C. Cosar and L. Julou¹ had shown it to be active against *Trichomonas vaginalis* in vitro and in mice, and P. Durel and colleagues² reported on its efficacy in curing trichomoniasis in patients of both sexes. They gave combined oral and local treatment to their women patients, but in 1960 excellent results in women with oral treatment alone were reported from several centres.³⁻⁶ Metronidazole by mouth is now generally accepted as the drug of choice for the treatment of trichomoniasis.

The therapeutic range of the drug was increased in 1962, when D. L. S. Shinn⁷ found it to be highly effective in treating Vincent's gingivitis. This led to an investigation into any possible effect of the drug on *Treponema pallidum*. Many patients attending venereal disease clinics are treated for trichomoniasis, which is usually sexually transmitted. Some of these patients may be incubating syphilis, and it is obviously important to know if metronidazole in the dosage usually given can destroy *T. pallidum*.

M. Scott-Gray and M. Murrell⁸ had previously shown that metronidazole 1.8 g. in 48 hours had no effect on a patient with primary syphilis. In 1966 A. R. Yobs and colleagues⁹ found that relatively large doses had no effect on the course of syphilis in rabbits. Two recent papers cast further light on this important problem. A. H. Davies¹⁰ treated six patients with secondary syphilis with doses of metronidazole ranging from 13.5 g. in five days to 34 g. in nine days. The local lesions healed and material from these patients showed disappearance of *T. pallidum* on dark-field examination. A. E. Wilkinson and his colleagues¹¹ showed that sera from patients under treatment for trichomoniasis may immobilize *T. pallidum* (Nichols strain) in vitro, but treatment of a patient with primary syphilis (positive on dark-field examination) with 200 mg. metronidazole three times daily for seven days did not heal the lesions, and *T. pallidum* was still detected at the end of the course.

It seems that the ability of metronidazole to eliminate *T. pallidum* depends on the daily dosage level: the organism

will survive 600 mg. of the drug but will be destroyed by 2 g. Thus the dosage of metronidazole usually employed for trichomoniasis does not appear to be treponemicidal. However, until more investigations have been carried out it would be wise for the venereologist to withhold metronidazole from patients who may be incubating or in the early phase of syphilis, until that diagnosis has been confirmed.

More Retroperitoneal Fibrosis

Though first described over 60 years ago, interest in retroperitoneal fibrosis has grown since its reported association with the drug methysergide.¹⁻³ There are now reports of over 200 cases, and the evidence suggests that it is being increasingly recognized. For example, in a recent series of 14 patients encountered in as many years in Birmingham,⁴ no fewer than ten were seen after 1963. This may be due to better awareness of the protean manifestations of a curious disease or to the increased activity of some aetiological agent as yet unknown.

There is no general agreement on what constitutes the syndrome of retroperitoneal fibrosis, and some authorities would exclude localized plaques of fibrosis. But it might be defined as a chronic fibrosing process which usually starts in the pelvis or lumbar region, and in the majority of cases spreads to the ureters. The disease attacks their walls though patency is maintained. Mediastinal fibrosis⁵ can also occur, and discrete fibrous masses may be found at the hilum of the lung and even in the lung parenchyma. Arteries, veins, and lymphatic channels may be compressed by fibrosis, so that a wide variety of ischaemic and obstructive lesions result. The usual history is of vague abdominal pain and backache, often radiating into the groins, with sooner or later signs of impaired renal function and hypertension. Epididymal swelling, hydrocele, and leg oedema may result from obstruction of veins in the pelvis, and in some patients the arterial supply to the lower limbs may be jeopardized. Less commonly, mediastinal fibrosis may have such diverse consequences as facial oedema, coronary ischaemia, pericarditis, and pleurisy. In addition there are such indications of the generalized nature of the disease⁶ as loss of weight, anaemia, a raised erythrocyte sedimentation rate, and increased levels of γ -globulin in the serum. While no doubt most patients will be seen by genitourinary surgeons or by physicians concerned with renal disease and hypertension, it is clear that no one, whatever his specialty, can afford to ignore the syndrome, and this is borne out by the fact that two of the patients in the Birmingham series presented as orthopaedic problems.

Retroperitoneal fibrosis may be a self-limiting condition,⁷ and spontaneous remission has been recorded.⁸ But in some cases it is progressive and fatal. Recognition is all the more important because, once the condition is thought of, diagnosis in the average case is not difficult and treatment is often rewarding. Hypertension with a history of abdominal pain,

a raised blood urea and erythrocyte sedimentation rate, and abnormalities in the plasma proteins, especially if there are other seemingly bizarre clinical features, should suggest the need for pyelography, especially by the retrograde route. The features are characteristic¹: delayed excretion of dye, with hydronephrosis and hydroureter above an obstruction, which is commonly in the mid-lumbar region or at the pelvic brim, and medial deviation and irregularity of the ureter at the site of obstruction. In difficult cases lymphangiography may also be valuable. Operation to free the ureters is often strikingly successful, though further obstruction may occur, and in some patients an affected segment of ureter has had to be resected.

What is the nature of retroperitoneal fibrosis? Histological examination of excised tissue has shown a wide variety of cell types, and in some cases vasculitis has been a prominent feature. There seems little doubt that an immunological reaction to a variety of sensitizing agents is the likely mechanism, and in some cases an autoimmune type of response is probable.⁹ The association with methysergide suggests a drug sensitivity, but so far no other drug has been implicated. Sometimes the condition appears to have been initiated by local infection or by haemorrhage in association with blood diseases.⁴ In a few cases the fibrosis represents an intense fibrotic response to malignant disease.¹⁰ But most must still be labelled "idiopathic," and they represent a challenge which will no doubt be met by careful clinical appraisal of new cases and by the efforts of immunologists.

Mental Handicap and the Family

Most undergraduate and postgraduate teaching on mental subnormality concentrates on diagnosis and phenomenology and gives little time to the study of the families of subnormal children and the stresses to which they are exposed. However, the interested doctor is aware that despite the common sense and compassion he brings to bear on the family's situation he needs to be better informed. He feels the lack of a broader background of knowledge and of guidance when he seeks to alleviate the stresses inevitable within a family confronted by the tragedy of mental handicap. He needs to know how the handicapped child should be assessed and educated, how the services available are organized, and how to make use of them. Further, he should be aware of current opinion on how these services could be developed and improved. A number of recent publications^{1,2} have dealt with these matters, but what the practitioner requires is a succinct but comprehensive presentation of the information. A working party convened by the National Society for Mentally Handicapped Children has recently produced a short report which goes a long way to meeting these requirements.

In 1958 F. L. Masland and his colleagues⁴ came to the broad conclusion that many mentally subnormal children do better at home than in institutions, especially in the early years. Later J. Tizard and J. C. Grad suggested that, unless there were strong contraindications, "parents should be encouraged and helped" to care for mentally handicapped babies themselves. The working party accepted these views as a premise, but it was no doubt aware that beyond a certain point the burden of looking after a mentally handicapped child may threaten the well-being of the family, and in these cases institutional care may be the only answer. "For parents of older children the choice remains theirs. It is unfortunate

that, today, the parents who bring up a subnormal baby themselves are likely to have a hard time of it."³

The report examines the procedure whereby the school medical officer, acting on behalf of the local education authority, assesses children who may be subnormal at the age of about 5. It points out that no matter how skilfully this assessment is made the objective is primarily administrative and is directed at excluding the child from school rather than at making a constructive educational or therapeutic recommendation. The report also emphasizes the inadequacy of a single assessment at a single point in time. Child psychiatry has long recognized the value of the multidisciplinary team approach for the diagnosis, assessment, and management of childhood disorders. This important concept is adopted and extended by the working party. Its view is that the assessments should be undertaken by such a team working in a co-ordinating centre planned and staffed jointly by the local authority and the National Health Service. The staff of such a centre should include medical specialists, educationalists, psychologists, social workers, and possibly parents. The team should work in co-operation with general practitioners and hand on information to them. Such an arrangement would give a family access to a centre where they could obtain authoritative diagnosis and assessment of subnormality and other handicaps, and under the same roof the accumulated knowledge of social and personal problems could be applied for the benefit of individual cases.

The report describes how provisions for the care and management of handicapped children vary from area to area throughout Britain. Greater co-operation between local authorities, hospital authorities, and voluntary societies is necessary before services can be integrated and rationalized so that more effective use is made of existing resources. Essential services such as pre-school facilities for subnormal children, training centres, and accommodation for short-term residential care to cover holidays or family crises are missing or inadequate in some parts. Planning for the future should ensure that these gaps are filled.

However, comprehensive outside services of this kind supply only part of the help that families need. The report goes on to indicate what needs to be done nearer home to relieve the burden of those who have handicapped children. They need help in getting suitable living. Financial assistance, when applicable, should include increased grants from the National Assistance Board, income tax relief, grants for laundry or home nursing, and subsidized holiday care. In addition to short-stay residential units, crèches and day nurseries should be widespread.

Counselling is of crucial importance. In the hands of the uninformed it may tend only to increase distress. Disclosure is a painful and delicate task, and, however carefully conducted, it may lead to an unfavourable reaction in the parents. It has been shown that a proportion of parents are critical not only of the way in which the disclosure was conducted but of the subsequent advice and help they had received.^{5 6}

Parents need a patient and sympathetic hearing and well-informed answers to their questions. They need genetic counselling and advice about family planning. They will wish to know how they can help with play activities; they will want advice about education, speech development, and training in social behaviour. The family will also need help with its own adjustment to handicap, with its own attitudes and reactions. If the counsellor has both the training and judgement to know not only when but how to explain the child's condition and is also capable of offering informed advice on the problems outlined above, the family will be the more likely to accept the situation realistically and to deal with it effectively, while adverse reactions such as rejection, over-compensation, or overwhelming feelings of guilt and conflict within the family may be avoided or attenuated.

Visible Alternatives

What is the best treatment for the ailing Health Service? Should it be radical, symptomatic, or both? What other ways are there of finding money and administering the Service? Taking up Mr. Enoch Powell's contention that "what is necessary is a visible alternative,"¹ the *B.M.J.* has recently examined some of the possibilities. Experts in economics and related fields have discussed, among other solutions, a nationalized health corporation, decentralizing administration, a Parliamentary Committee on the Health Service, and the prospects for private health insurance. All the articles in this series, together with a medical summing up by Sir Robert Aitken, have now been collected into a booklet, which was published this week.²

Most of the contributors conclude that for various reasons the National Health Service cannot now be abandoned. Nevertheless, as Sir Robert Aitken points out in his thoughtful and provocative concluding essay, "some large and important practical improvements . . . lie to hand." The first of these should be a serious attempt to lessen central control over hospital boards. Boards should be given considerable responsibility for the design and construction of buildings and allowed to spend their recurrent grants as they wish. Sir Robert's second main proposal is for a Health Service Ombudsman, possibly associated with a Select Parliamentary Committee on Health, through which valuable and unbiased evidence would flow to Parliament. Sir Robert argues that the creation of an Ombudsman would take away the strain of the petty Parliamentary Question without lessening the standards and accountability inherent in a public service. Thirdly, experiments should be made in ending the tripartite structure of the Service—for example, by associating general practice with hospital practice. In this way "urban general practice would come alive again." Finally, he argues, more value must be got out of the same amount of money, both by sensible economies and by greater efficiency.

Unlike some of the alternatives proposed, this last suggestion would cost nothing and could be put into practice more or less immediately. Nevertheless, it is only one of several important changes that must be made if our Health Service is to compare with those in many other countries. All who are striving to improve the Service will find much useful guidance in this booklet.

Papers and Originals

Prevention of Rh-Haemolytic Disease*

C. A. CLARKE,† M.D., SC.D., F.R.C.P.

[WITH SPECIAL COLOUR PLATE FACING PAGE 8]

Brit. med. J., 1967, 4, 7-12

The story of the Liverpool research to prevent Rh iso-immunization is a simple one, and its origins were unusual in that they stemmed from breeding Lepidoptera.

Single Gene Differences and the Origin of a Supergene in *Papilio* Butterflies

Plate 1 shows the Swallowtail butterfly *Papilio machaon*, which in this country flies in the Norfolk Broads. All that needs to be noted is that it is yellow. Plate 2 shows a related species, *Papilio asterias*, common in North

distasteful model, *Parides coon* (Plate 5b). In both model and mimic it should be noted that (1) tails are present, (2) the white "window" of the hindwing is small, and (3) the body is yellow. Plate 5c is a non-mimetic form (*agenor*) of *P. memnon*, and breeding data appear to show that *achates* is dominant to *agenor* and that there is a single gene difference between the two forms. However, the matter is not as simple as this, for occasionally rearrangements take place, and Plate 5d shows a bred *memnon* insect where, though tails are present and the "window" is small, yet the body is black. This suggests that crossing-over has occurred and that the single gene is in fact a supergene composed of several closely linked loci (Fig. A).

FIG. A.—Chromosomal arrangement of insects (a) and (d) in Plate 5.

America, and it will be seen that here the ground colour is black. In 1953, having earlier learnt how to hand-pair swallowtails (Clarke, 1952), hybridization between *P. machaon* and *P. asterias* was carried out (Clarke and Knudsen, 1953). The cross proved fertile, and in Plate 3 it will be seen that the F_1 hybrid was black and remarkably similar to the American parent. Though the hybrids were sterile *inter se*, yet it was possible to obtain back-crosses, and in the one to *P. machaon* there was clear-cut segregation (Plate 4), indicating a single gene difference as regards ground colour between the two species, black being dominant to yellow. During this study I met P. M. Sheppard, and it was decided to use the hand-pairing technique to investigate the phenomenon of mimicry, first in an African species, *P. dardanus* (Clarke and Sheppard, 1956, 1958, 1959, 1960), and later in a South-east Asian species, *P. memnon* (Clarke *et al.*, in press).

In mimicry certain butterflies, particularly tropical ones, resemble others, the models (often belonging to quite different families), which are distasteful to predators, particularly birds. Models and mimics usually fly together, and birds which have sampled the distasteful models tend to leave the mimics alone even though these are highly palatable. Plate 5a shows a mimetic form (*achates*) of *P. memnon* together with the

It was this type of finding (originally in *P. dardanus*) and the many examples of genic interaction in the *Papilio* species which directed our attention to the rhesus blood group system, where crossovers probably account for the rarer genotypes and where there is a marked interaction between the Rh and ABO systems.

Rh and ABO Interaction

Levine (1943) first pointed out that there is a deficiency of ABO incompatible matings—that is, those where the wife cannot safely be transfused with her husband's blood—in families where children with Rh-haemolytic disease have occurred. This is because ABO incompatibility as between mother and foetus markedly protects against Rh immunization. The original observation has since been amply confirmed, and the most reasonable explanation is that ABO incompatible foetal red cells are destroyed in the maternal circulation by the naturally occurring anti-A or anti-B before they can sensitize the mother against the D antigen (the elimination probably taking place in the liver). This theory has support from the experimental work of Stern *et al.* (1956). They injected Rh-positive blood into Rh-negative male volunteers and found much higher titres of anti-D when compatible ABO blood was injected than when incompatible blood was used. Another observation made by them (Stern *et al.*, 1961) which turned out later to be very relevant to our research was that when Rh-negative ma-

* Lumleian Lecture delivered at the Royal College of Physicians of London on 3 May 1967.

† Professor of Medicine, University of Liverpool; Consulting Physician, Liverpool Royal Infirmary and Broadgreen Hospital, Liverpool. Director, Nuffield Unit of Medical Genetics, University of Liverpool.

volunteers were injected with Rh-positive red cells coated with complete anti-D the men did not form immune anti-D.

To test further Levine's original observation, in 1958 we carried out in Liverpool a family study in order to determine the ABO group of the sensitizing foetus in families where there was Rh-haemolytic disease (Clarke *et al.*, 1958). The number of families investigated was 91, and of these the parents of 23 are incompatible on the ABO system. In 14 of these 23 families we were able to determine the sensitizing foetus with certainty and all were compatible with the mother on the ABO system. The probability of this occurring by chance alone is less than 1 in 500. Additional support for protection by ABO compatibility, derived from this same series, was the marked deficiency of matings where the mother was O and the father was A (16 as against 33 where the mother was A and the father was O), whereas a 1:1 ratio would be expected if no protection existed. Nevertheless protection is not invariable—in a different study we did find one ABO incompatible sensitizing foetus, and it has also been described by other authors (and in Table II).

Shortly after this 1958 paper it occurred to us that it might be possible to mimic the protection afforded by ABO incompatibility by giving the mother anti-D after delivery, thereby destroying any Rh-incompatible foetal cells (which we assumed had at some time crossed the placental barrier) before they had time to sensitize her. This idea was put forward at a meeting of the Liverpool Medical Institution by Finn (1960), and by this time we had already begun work to test the hypothesis. This involved injecting Rh-negative male volunteers with chromium-tagged Rh-positive cells and later giving high titre anti-D as an infusion of plasma (Finn *et al.*, 1961). It was found that when complete (saline) antibody was given enhancement of immune antibody was produced in the "treated" compared with the controls, but that when incomplete (albumin) anti-D was used then significant protection was obtained (Clarke *et al.*, 1963). Though protection in men therefore seemed possible it was still uncertain whether the technique would work in mothers, but this problem was made much easier when it became possible to detect foetal cells in the maternal circulation, and this is next discussed.

Foetal Cells in the Maternal Circulation

Kleihauer *et al.* (1957) showed by means of an acid elution technique that it was possible to demonstrate and count foetal cells among a population of adult red cells, the latter appearing as ghosts and the former as dark refractile bodies. Goursky *et al.* (1959) first used this method to detect foetal cells in the blood of women after delivery, and it was their paper which decided us to use the technique in our work. Our investigations showed that, while foetal cells can be demonstrated occasionally in the maternal circulation throughout pregnancy, they occur much more often and in greater numbers near or after delivery. Again, and most important from the protection point of view, the number of foetal cells found in the maternal circulation near or just after delivery correlated well with the frequency of the formation of immune anti-D in the mother six months later (Woodrow *et al.*, 1965; Woodrow and Finn, 1966). It was these findings together with our results in the volunteers which strengthened our view that giving anti-D to mothers after delivery might be effective. We therefore decided to carry out clinical trials, but before discussing these it is necessary to mention some important points relating not only to our work but also to that of others.

(1) Counting of Foetal Cells and Accuracy of the Acid Elution Technique

In most of our work the foetal cell score has been the number of foetal cells found in 50 low-power fields, and very roughly

we assess that a score of 1-4 implies less than 0.25 ml. of foetal blood in the maternal circulation, a score of 5-60 means approximately 0.25-3 ml., and a score of over 60 means more than 3 ml. of foetal blood (Clarke *et al.*, 1963; Woodrow *et al.*, 1965). In this paper the term "significant bleed" means either of the last two.

A more accurate method of scoring is to relate the number of foetal to the number of adult cells, and Table I shows the result in our laboratory of a test carried out "blind" from material sent to us by Professor P. L. Mollison in which varying proportions of adult and foetal cells (samples A-E) were mixed. It will be seen that though our results (Mollison, personal communication) are not particularly impressive, yet the findings are in the right order of correctness though we failed to detect any cells in the most highly dilute mixture (sample D).

TABLE I.—Accuracy of the Acid Elution Technique in Our Laboratory (See Text)

	A	B	C	D	E
No. of foetal cells observed (two observers)	3+4	0+0	60+58	0+0	0+0
Ratio of total foetal cells to total number of adult cells scanned (our estimate) ..	1/50,000	—	1/3,000	—	—
Correct result	1/17,000	0	1/1,070	1/37,000	0

(2) Difficulties in Scoring

There are several inherent difficulties in the interpretation of the slides, because the acid elution technique does not distinguish between maternal and foetal Hb F. Maternal Hb F levels are increased in thalassaemia and in some other haematological disorders, and there may also be an increase in maternal Hb F during pregnancy. False positive results may also occur in association with a marked reticulocytosis. With experience it is usually, though not invariably, possible to identify those conditions with a high maternal Hb F, because the latter is usually unevenly distributed among many cells rather than concentrated in a few, as it is in a true transplacental haemorrhage (Woodrow and Finn, 1966). In a few cases this distinction is, however, not possible (see W.H.O. Report, in press).

(3) Foetal Cell Count and ABO Incompatibility

Table II shows well the effect of ABO incompatibility in reducing the foetal cell count in 1,000 Rh-negative primigravidae, the information kindly being supplied by Dr. C. C. Bowley, of Sheffield, who has been working with us in the group project (see *Brit. med. J.*, 1966). The reason why foetal cells survive in some of the ABO incompatible cases is because destruction is not always complete, and also because in certain cases the blood has been examined so quickly after delivery that there has not been time for the cells to be eliminated.

TABLE II.—Comparison of Foetal Cell Counts in Foeto-maternal ABO Compatibility and Incompatibility (See Text)

Foetal Blood	Significant Bleeds		Insignificant Bleeds		No Bleed		Total
	No.	%	No.	%	No.	%	
ABO compatible: D-positive	85	18.6	184	40.2	189	41.2	458
D-negative	70	20.2	147	42.2	131	37.6	348
ABO incompatible: D-positive	5	4.2	28	23.5	86	72.3	119
D-negative	3	4.0	20	26.7	52	69.3	75
Total ..	163		379		458		1,000

cells (Freda and Gorman, 1962; Freda *et al.*, 1964). Rather they tried to put to practical use the finding of Smith (1909) that mixtures of diphtheria toxin and antitoxin, with antibody in excess, did not immunize when injected. Later it had been shown that if specific antibody is given passively to an individual subsequent injections of antigen completely fail to immunize, provided that there is a state of antibody excess at all times. Because of this, in the early New York experiments with male Rh-negative volunteers, the antibody injection was given before the Rh-positive cells were injected (Gorman *et al.*, 1963; Freda *et al.*, 1964) (see McConnell, 1966, and also Clarke, 1966).

There may, in fact, be no very great difference between our rationale and theirs, but the important contribution which the U.S.A. workers made was the introduction of anti-D gammaglobulin rather than plasma. Anti-D gammaglobulin carries no risk of jaundice, and being given intramuscularly is a much more convenient preparation to administer, and as soon as we knew of the U.S.A. advance we switched over to gammaglobulin, which has been made for us from the plasma of our hyperimmunized male volunteers by Dr. W. d'A. Maycock, Mr. L. Vallet, and their colleagues at the Lister Institute.

Clinical Trials

In May 1964 we decided to give, within 48 hours of delivery, 5 ml. of gammaglobulin containing incomplete anti-D (usually with a titre of between 1 in 1,280 and 1 in 4,096 in albumin with R_{17} cells). This was given intramuscularly to alternate primiparae in whom the foetal cell score was 5 or more, and we decided to analyse this trial when about 70 controls and 70 treated had been followed up for at least six months. The results were highly satisfactory and were reported last year (*Brit. med. J.*, 1966). Of the 78 treated none had for certain produced immune antibody whereas 19 of the 78 controls had done so.

Similar trials, though not restricted always to primiparae and to "high risk" cases, have been in progress in U.S.A. and Germany, and Table III gives the overall results, so far as we know them, up to July 1967. It will be seen that at six months only one woman has become immunized in the treated group, a much better result than in our male volunteers. However, the controls pose some problems. It will be seen that in the various centres there is considerable heterogeneity among them and we do not know for certain the cause of this. While the figure in the "Liverpool group" is explicable because high-risk cases only were treated, yet this was not so elsewhere; but it may be that different obstetrical practices are responsible for greater or less foeto-maternal bleeding. In this connexion it is of interest that Worledge (1966) has shown in Nigeria that the Rh-immunization rate is only about one-third of what it is in this country, and this is probably not to be explained by the lack of antigenicity of the common R^0 antigen, since the

* Though there is no doubt about the complete failure in this case, it may be instructive. The patient developed a sharp local reaction to the anti-D gammaglobulin, and we then learnt that she had received early in pregnancy a prophylactic dose of anti-rubella gammaglobulin. Whether this has any bearing on the failure is being investigated. (See Wilson and Steinberg, 1965.)

immunization rate after transfusion with Rh-positive blood is about the same as it is here.

Persistence of Injected Anti-D Gammaglobulin

The U.S.A. group have carried out tests to see how long the passive antibody can be detected and Table IV shows their results. We also seldom find passive antibody after six months, but occasionally traces have been detected for longer by an enzyme technique. For example, at the time of the original analysis of our Liverpool group clinical trial (*Brit. med. J.*, 1966) there were three cases among the 78 treated where it was uncertain whether it represented only the remains of the injected anti-D. This in fact turned out to be the case since in all three mothers the antibody eventually disappeared, though in one case it was thought to have lasted for as long as 13 months.

Subsequent Pregnancies (all Centres) up to June 1967

Though the six months' results were highly satisfactory there was always the possibility that the anti-D was only masking immunization and that in the next pregnancy the treated women would produce overt antibodies and "catch up" with the controls. The data in Table V strongly suggest that this is not the case, because none of the women who received the anti-D gammaglobulin after their previous preg-

nancy has, in fact, produced immune rhesus antibodies after having had a subsequent Rh-positive ABO compatible baby, whereas 15 further cases in the controls have done so. Nevertheless, larger numbers of second pregnancies are needed before concluding that the prophylaxis is really of the very high order it appears to be at present.

Second Liverpool Trial

Having determined that 5 ml. of anti-D gammaglobulin protected the high risk cases, we decided in June 1966 to start a second trial, using only 1 ml. of anti-D, this again being given to alternate primiparae, but now only to those who had a foetal cell score of 0-4 cells, inclusive. Using these criteria, we knew

we should get many more cases, and it seemed highly likely that the immunization rate would be much lower. The indications are that this is so, since at the time of writing (July 1967) 3 out of the 54 controls have become immunized compared with one out of 51 treated, these all having been followed up for six months or more. The treated woman who produced the antibody did so between the fourth and seventh month of a second pregnancy. Whether this means that 1 ml. of the Liverpool anti-D gammaglobulin is too small a dose (see below), or whether the mother is one of the rare cases where antibody is produced in the first "at risk" pregnancy (to which this pregnancy approximates), remains to be seen. If the former is the case more antibodies will develop in the treated in this trial.

Because of the good results from the five Liverpool maternity units in the first trial, all primiparae in these hospitals where the cell score is 5 or more are now being given 5 ml. of anti-D gammaglobulin.

Indications for Prophylaxis in Rh-haemolytic Disease

The feasibility of a procedure is no indication for carrying it out, and, though there seems little doubt that the giving of anti-D is prophylactic, yet it has been suggested that the treatment is not without risk, and that the immunization of large numbers of volunteers and the mass inoculation of Rh-negative women is not justified. The critics feel that this is particularly so because only a small proportion of women at risk become immunized, and, even if they do, modern methods of treatment mean that the majority of children are saved. This clearly needs consideration and the risks must first be assessed.

Risks to the Mothers

In our experience the initial injection is safe. We have observed very occasionally local reactions, sometimes associated with fever, for 24 hours, but these are most exceptional and usually there is no upset of any kind. With anti-D gammaglobulin there appears to be no risk of causing homologous serum jaundice, since if the virus is present it is eliminated in gammaglobulin prepared by the alcohol or other fractionation procedure (Mollison, 1967). We have twice given it in error to women who were later found to be weakly Rh-positive (D^u) and no reaction of any kind was observed, and probably there would be no serious trouble if the injection were given to women who were of the more usual Rh-positive types. There remains the question of the possibility of the mother becoming immunized to the gammaglobulin itself. We have investigated this with the help of Dr. Sylvia Lawler, who has tested the Gm groups in 20 of our treated women and in 20 controls, both matched approximately for the size of foeto-maternal "bleed." No anti-Gm was found in the controls, but it was in one treated case and the details of this are as follows:

Anti-Gm Study.—Mrs. N., a treated mother, has anti-Gm antibody, of Gm^{a+} specificity, in her serum not present before delivery. She herself is Gm^{a-} and so is her husband. Her mother, however, is Gm^{a+}, and Mrs. N. may have been originally sensitized from her mother, our gammaglobulin acting as a secondary stimulus.

It seems certain that here the gammaglobulin was responsible for the development of the overt anti-Gm, though it is possible that the primary stimulus was derived from the mother of the treated woman. However, the risks of a serious anaphylactic reaction if gammaglobulin needed to be given again in a subsequent pregnancy appear to be small, severe anaphylaxis being likely to occur only if the patient is hypogammaglobulinaemic (Grubb *et al.*, 1965).

When considering risks it seems right to take into account the views of patients. They in general are in no doubt about

wanting prophylaxis, and it is in fact our controls who sometimes complain of being guinea-pigs.

Risks to the Volunteers

Deliberate immunization of Rh-negative volunteers carries the slight risk of homologous serum jaundice, but this can be minimized by injecting washed Rh-positive cells and always deriving these from a donor who has been known to have given blood to at least 10 recipients all of whom have been kept under supervision for a period of six months and not developed jaundice (see W.H.O. Report, in press). Nevertheless, the hazard remains and there is a genuine difference of opinion about the advisability of immunizing men on a large scale at this stage. The view of many is that supplies of anti-D from women who have been naturally immunized, or from men and women who have developed antibodies as the result of transfusion, should be used first. This is reasonable, but there are often difficulties in tapping these supplies, and they are in any case a dwindling source. The contrary view is that if protection can be obtained by the use of small quantities of anti-D when this is hyperimmune (donors repeatedly restimulated) then it would be preferable to have small numbers of Rh-negative volunteers in each region and the necessary supplies obtained by plasmapheresis. The extent of the problem if this were the procedure adopted is as follows. If it is assumed that for every million of a Caucasian population 1,600 Rh-negative women will give birth each year to an Rh-positive ABO compatible infant and that the suppressive dose of anti-D gammaglobulin is 1 ml. (but see below), then about 90 litres of anti-D antibody-containing plasma will be needed annually. Using plasmapheresis and assuming that each donor gives half a litre of plasma 12 times a year, 15 donors with acceptable anti-D antibody titre would be required per million of the population.

We think that the risks outlined above are very small and should be accepted. In all prophylactic inoculations large numbers of people are injected unnecessarily, but one of the chief functions of a clinician is to allay anxiety, and the evidence strongly suggests that Rh-negative women need no longer be anxious about their blood group. Also, though many babies are saved by medical care, yet the stillbirths remain a problem, and in general there is a great deal of distress in a not inconsiderable number of families and it seems likely that this can be avoided.

Lastly, the fact that exchange transfusion is feasible (though expensive, time-consuming, and not always successful) is no indication for preferring it to stopping the trouble at the source.

Problems Remaining to be Solved

(1) Latest Time at Which Gammaglobulin can Effectively be Given

In our trials the anti-D has been given within 48 hours of delivery and in the U.S.A. up to 72 hours. Since, for a variety of reasons, "at risk" patients might not be identified quickly, it is important to find out how long after delivery an injection of gammaglobulin is effective, and we are at present planning a trial in volunteer men to see if it is still protective when given a week after the injection of Rh-positive cells.

(2) Prophylaxis During Pregnancy

The results of the clinical trials to date giving the injection after delivery have been better than anticipated. It may, however, be that on occasion an effective immunizing dose of Rh-positive cells crosses the placenta during pregnancy. Zipursky *et al.* (1965) have shown that it is a safe procedure to give anti-D gammaglobulin during pregnancy, and while

we do not know whether this is protective yet it does not cause anaemia in the baby, though the Coombs test is occasionally positive. If failures with the conventional treatment after delivery do occur, their work would have great practical importance.

(3) Duration of Protection

The length of time during which injected anti-D affords protection is uncertain, but Chown (1966, personal communication) gives details of an interesting experiment which is summarized here. Three groups of six men in a local penitentiary were injected with 2 ml. of foetal Rh-positive blood. Then, 48 hours later: group (a) received 5 ml. of anti-D, group (b) received 1 ml. of anti-D, and group (c) received 1 ml. of commercial gammaglobulin.

Immune antibody production six months later was: group (a) 0/5 (1 man released), group (b) 0/6, and group (c) 3/6. At this time a further 2 ml. of Rh-positive foetal cells was given to each man.

Immune antibody production 10 months later was: group (a) 0/1, group (b) 0/3, and group (c) 5/5 (9 men released).

Chown and his colleagues interpreted these results as supporting the concept of a suppressive effect on the potential specific antibody-forming cellular system, and as being in line with the experimental work of Finkelstein and Uhr (1964) and Rowley and Fitch (1964). The Canadian workers go further and think that the protection may last even after the antibody is no longer detectable.

On the other hand, Freda *et al.* (1966) showed that two out of eight of their previously protected male volunteers were still (10 months after their last injection of anti-D) capable of producing immune antibody when given a fourth and fifth antigenic stimulus *without* the anti-D gammaglobulin cover. The matter therefore remains open, but is of great current interest not only in this field but also in others such as in the prevention of autoimmune disease and in tissue transplantation.

(4) Optimal Dose of Anti-D Gammaglobulin

This is the most important current problem. Clearly it is meaningless to talk of 5 or 1 ml. of gammaglobulin and its strength must be assessed in some way. Titre has generally been used in the past, but this for technical reasons varies greatly in different laboratories, and, moreover, it only measures the amount of antibody which is combined with antigen on the red cell. Since the reaction between antibody and antigen is reversible, there is always some free antibody present in the plasma, of which titre takes no account. Nevertheless, this fraction may be important if central inhibition of the antibody-forming cells is of more account in preventing immunization than the blocking of the antigen sites on the red cells (see above). Therefore the total amount of anti-D in $\mu\text{g. per ml.}$ is probably the most reliable measure, and it can be estimated by various labelling procedures (Hughes-Jones, 1967; Goldsmith *et al.*, in press).

However, for the present, since the precise method of protection is unknown, it seems best to estimate where possible both the titre *and* the total amount of anti-D present.

It is uncertain how the dose of anti-D in $\mu\text{g. per ml.}$ has been related to its effectiveness in suppressing immunization, but some information is available. In the first clinical trial carried out by the Liverpool group, 5 ml. of gammaglobulin containing incomplete anti-D with a titre of usually between 1 in 1,280 and 1 in 4,096 in albumin with R_{2r} cells were used. Though the concentration of this is not known, it is believed to have been similar to later ones that have been estimated, and if so the 5 ml. contained about 1,000 $\mu\text{g.}$ of anti-D, and this dose

appears to be nearly always protective. (For this and other assessments of anti-D in $\mu\text{g. per ml.}$ I am indebted to Dr. N. C. Hughes-Jones.)

However, both the New York and Winnipeg groups (W.H.O. Report, in press) have experimental evidence that a smaller amount is also effective. The former found that 0.1 ml. of their anti-D preparation protected four volunteers when given after 10 ml. of blood on six occasions, and the latter report that 1.5 ml. of another anti-D preparation protected 12 volunteers when injected with 2 ml. of blood. The anti-D concentrations of these two gammaglobulins, though also unknown, are thought to be of similar potency to later ones from the same centres, and if this is so the amount injected was of the order of 150 $\mu\text{g.}$ of anti-D in the New York experiments and 300 $\mu\text{g.}$ in those of Zipursky and his colleagues in Winnipeg. On the other hand, we have to remember that in her second pregnancy an immune antibody appeared in a woman in our second trial who had been given 1 ml.—that is, about 200 $\mu\text{g.}$ —of anti-D.

At lower doses it would seem from work carried out in Germany and New York (see also W.H.O. Report, in press) that a dose of the order of 10 $\mu\text{g.}$ of anti-D antibody is insufficient to prevent immunization. While these are only interim results they may serve as a basis for further experiments, but one fact is quite clear—namely, that the U.S.A. gammaglobulin is considerably stronger than that which we are using. Additional evidence that this is so is found when testing for passive antibody about 48 hours after a 1-ml. injection. Robertson (personal communication), using this dose of U.S.A. gammaglobulin, often finds a titre of 1 in 8, while, on the other hand, our 48-hour antiglobulin test with 1 ml. of the Lister product is always negative, the passive antibody being detected only by an enzyme technique. On using 5 ml. of the Lister preparation, as in the first Liverpool trial, our 48-hour antiglobulin titre is usually about 1 in 4. A particular case met with recently also gives some preliminary information about dosage (Gilliver, 1967).

A 21-year-old primigravida, blood group A rhesus (D) negative with no antibodies detectable at 34 weeks, was admitted to hospital on 12 September 1966.

After 54½ hours, an 8 lb. 5 oz. (3,770 g.) male infant was born by assisted breech delivery. His condition was satisfactory at birth but later the respirations became shallow and grunting and convulsions began, first right-sided and later generalized. About 24 hours after birth the infant's haemoglobin was 9.8 g./100 ml. and a blood film showed intense erythroblastosis. The baby's blood group was A Rh-positive and the direct Coombs test was negative.

Maternal blood was found to contain vast numbers of foetal cells, and this was confirmed by mixed-field agglutination with a saline anti-D serum. In a blood sample sent to Liverpool it was estimated that there were roughly 3,400 foetal cells per 50 low-power fields, and this was probably equivalent to about 170 ml. of foetal blood.

Seventy-two hours after delivery 5 ml. of gammaglobulin obtained from Liverpool was given, and 36 hours later the volume of foetal blood had fallen to about 80 ml., and at this time the Coombs test was positive. Free antibody at a titre of 1 in 4 was still present nine days after the injection, but the foetal cell score was 3 (representing less than 0.25 ml. of foetal blood) and the direct Coombs reaction had become negative.

Three and seven months later the follow-up revealed no antibodies detectable by the saline, albumin, Coombs, or enzyme techniques.

The baby improved satisfactorily after a transfusion of 85 ml. packed cells.

It will be interesting to see what happens in a subsequent pregnancy, but 5 ml. of the Liverpool gammaglobulin is evidently effective in clearing a very large T.P.H., and if this is, as we think, important in protection then it may well be that 5 ml. is an unnecessarily large dose in the majority of cases (see also Mollison and Hughes-Jones, 1967). But it must be remembered that in mismatched transfusions only about 50% of Rh-negative individuals are immunized by giving 1 pint (570 ml.) of Rh-positive blood (Mollison, 1967).

Until the mechanism of suppression of primary immunization is more precisely known, factors other than anti-D concentration and titre may be important. Thus it is possible that there may be variation in the biological activity of anti-D antibody obtained from different donors, and anti-D preparations are now made from pools of at least 10 donors. It will be interesting to see the results of clinical trials where the relative effectiveness of anti-D antibody derived from mothers who have had severely affected babies but who have not been deliberately restimulated is compared with that from donors who have been.

Summary

Genetic studies in *Papilio* butterflies, particularly those concerned with the evolution of mimicry, led to our interest in the Rh blood groups. Here, as in the mimetic butterflies, the various phenotypes are controlled by a series of closely linked genes (a supergene) and, again as in the butterflies, there are marked genetic interactions. The most important of these, described by Levine in 1943, is that ABO incompatibility as between mother and baby is nearly always protective against rhesus immunization of the mother. The mechanism of this is uncertain, but the most reasonable explanation is that any rhesus-positive foetal cells which have crossed into the maternal circulation are destroyed by the mother's naturally occurring anti-A or anti-B before they have had time to stimulate the production of Rh antibodies.

It occurred to us that it might be possible to imitate this by giving anti-D to Rh-negative mothers in the far more usual situation where mother and baby were compatible on the ABO system, and the idea was first put forward in 1960 at a symposium on medical genetics at the Liverpool Medical Institution.

Experiments on rhesus-negative blood-donor volunteers showed that protection could be achieved provided incomplete anti-D was given, and in these early experiments plasma was used from artificially immunized males. Concurrently with this research, the acid elution technique for the detection of foetal cells in an adult red cell population was used to show that transplacental haemorrhage was commoner at or near delivery, and, furthermore, that the greater the number of foetal cells in the maternal circulation just after delivery the more likely the mother was to produce immune Rh antibodies.

Similar work in the U.S.A., using anti-D in the form of gammaglobulin, which was much safer and more convenient, was first published in 1962, and after this we too used only anti-D gammaglobulin.

Details are given of several successful clinical trials carried out in this country, the U.S.A., and Germany, in which soon after delivery the mother is given an intramuscular injection of gammaglobulin containing a high titre of incomplete anti-D.

Definite proof that Rh immunization can be prevented by this technique will rest on the immunological state of the treated women, just after they have had a subsequent Rh-positive ABO compatible baby. To date the results in these subsequent pregnancies are very encouraging, and the evidence indicates that nearly all cases of maternal Rh immunization can be prevented.

The risks to mothers and to the male volunteers are discussed and mention is made of the problem of supplies of anti-D gammaglobulin if the prophylaxis is to be made generally available. Other problems which remain to be solved, particularly the optimal dose of gammaglobulin, are outlined.

Mortality of Bereavement

W. DEWI REES,* M.B., B.S., M.R.C.G.P.; SYLVIA G. LUTKINS,† B.SC.

Brit. med. J., 1967, 4, 13-16

"He first deceased; she for a little tried
To live without him; liked it not, and died"
—Sir Henry Wootton.

That bereavement is associated with an increased mortality rate for close relatives is an old concept that has only recently begun to receive statistical confirmation.

In 1959 Kraus and Lilienfeld reported that married people had a lower death rate at every age group than those who were widowed, single, or divorced and that there was a particularly high excess risk of mortality for young widowed people. Young *et al.* (1963) then tried to assess the "duration effect" of widowhood on the mortality of 4,486 widowers aged 55 and over and found that widowhood increased the mortality rate by about 40% in the six months following bereavement. Cox and Ford (1964) analysed data about 60,000 women awarded widows' pensions in 1927 and concluded that the mortality of widows is probably not exactly the same in each of the five years following bereavement and seems to be higher in the second year after bereavement. The need for further studies in this field was stressed by Kraus and Lilienfeld (1959) and by Young *et al.* (1963), and a survey was therefore made to assess the effect of bereavement on the mortality of close relatives in a small semirural community. This survey differed from those previously made in that it included close blood relatives as well as the widowed and because a total community study was made in an area where the investigator (W.D.R.) possessed a close personal knowledge of the people included in the survey.

Method

The survey was made in a defined area, centred upon the small market town of Llanidloes (pop. 2,350). The area was so defined that with very few exceptions all residents were patients of a single group practice. A small cottage hospital, a chronic sick unit, and an old people's residential home are situated within the area.

The name, sex, age, address, certified cause of death, and place of death of all those people normally resident in the area who died in the six-year period following 1 January 1960 were obtained from the county medical officer of health. The marital state of these people and the identity of those of their close relatives who also lived in the area were determined with the help of the practice secretaries and the secretary of the local cottage hospital. Those people were considered close relatives who were either a spouse, parent, child, or sibling. Those people who had no close relatives alive when they died were excluded from the survey. The remainder were matched by age, sex, and marital state with a similar control group known to have relatives living in the area. This was done by arbitrarily selecting alternate names from the relevant age/sex lists of the practice age/sex register. It was not found possible to match all the paired couples exactly for age or marital state, and five widowed people were paired with people still married. The identity of the close relatives of the control group was determined in a similar way for that of the survey group. In determining the subsequent mortality of close relatives in this

control group the assessment was made in each case from the time of death of the individual with whom the control had been paired.

Results

A total of 5,184 patients lived in the defined survey area; their age and sex distribution is given in Table I. During the period under review 488 residents died; 404 residents died within the survey area and 84 other residents died in hospitals or private homes outside the area; the age and sex distribution of these people is given in Table II. Of the 488 residents who died, 108 had no close relatives living in the area and they, together with the nine recorded as neonatal deaths, were excluded from the survey. The remaining 371 (76%) form the survey group; the age and sex distribution of this group is given in Table III. When the 371 residents forming the survey group died they had a total of 903 close relatives living in the area; the comparative figure for the control group is 878. The number and type of close relatives extant at the time of real or hypothetical death for both the survey and control groups are given in Table IV. The number of each type of relative who died in the years following bereavement is

Child ..	222 (25.3%)	188 (21.4%)	410 (46.7%)
Sibling ..	132 (15.0%)	141 (16.1%)	273 (31.1%)
Total ..	414 (47.2%)	464 (52.8%)	878 (100%)

Statistical Method

The following test was used to determine whether the proportion of deaths in the survey group was significantly greater than the proportion of deaths in the control group.

For large samples u is approximately normally distributed with zero mean and unit variance, where

$$u = \frac{p_1 - p_2 - \frac{1}{2}}{\left[pq \left(\frac{1}{N_1} + \frac{1}{N_2} \right) \right]^{\frac{1}{2}}}$$

which is algebraically equivalent to

$$u = a - \frac{rA}{N} - \frac{1}{2} \left[\frac{ABr(N-r)}{N^3} \right]^{\frac{1}{2}} = \sqrt{\chi^2}$$

using the customary notation for a 2×2 contingency table, and a correction for continuity.

A one-tail test is appropriate here, so a value of u greater than or equal to 1.64 will be significant at the 5% level. For

the 1% level the value of u is 2.33. For very small values of A and B exact values for the probabilities were obtained from *Tables of the Hypergeometric Probability Distribution* by Lieberman and Owen, but none of these small sample tests were significant.

The statistical significance of the differences in mortality recorded between close relatives in the survey and control groups during the first year of bereavement is given in Table VII.

All Close Relatives

The number of close relatives who died each year following bereavement is given in Table V. This shows that there is a considerable difference between the number of deaths recorded in the survey and control groups and that the difference is

FIG. 1.—Percentage of deceased people whose death was followed each year by the death of a close relative.

greatest during the first year of bereavement. During the first year 43 (4.76%) bereaved close relatives died compared with 6 (0.68%) in the control group. This difference in risk between the two groups was found to be highly significant at the 0.001% level. During the second year the comparative figures for the bereaved and control groups were 18 (1.99%)

and 11 (1.25%); the difference between these figures was not significant.

The difference between the groups is exemplified further by Fig. 1; this shows the percentage of deceased people whose death was followed each year by the death of a close relative. It shows that close relatives of 11.6% (43) of the survey group died within a year of bereavement and that the corresponding figure for the control group was only 1.6% (6). It also shows that while the mortality rate for the control group shows a relatively small fluctuation over the six-year period there is an apparent change in pattern for the survey group, and the mortality rate for the bereaved group remains higher than that of the control group for the first three or four years following bereavement.

The risk for male relatives was found to be greater than for female relatives. During the first year of bereavement 6.4% of the 391 male relatives at risk died, compared with 3.5% of the 512 female relatives. This difference in risk between the sexes was significant at the 5% level.

Widows and Widowers

During the first two years of bereavement the mortality rate for widowed people in the bereaved group was higher than for those in the control group. The difference between the two groups is shown in Tables V and VI. Of recently widowed people, 12.2% died during the first year of bereavement, 6.6% of those at risk died during the second year, and 2.5% during the third year. Though 12.2% of widowed people in the bereaved group died during the first year of bereavement only 1.2% of the control group died. This increase in risk for widowed people during the first year of bereavement was significant at the 0.01% level.

The mortality rate for widowers was considerably higher than the mortality rate for widows. During the first year of bereavement 19.6% of widowers and 8.5% of widows in the bereaved group died. This difference in risk between the widowers and widows was significant at the 5% level.

Of the bereaved widowers, 13.7% died during the first six months of bereavement, 5.9% died during the second six months, and 4.9% died during the following 12 months. This different mortality rate for widowers during the first and second six months of bereavement was significant at the 1% level and confirms the findings of Young *et al.* (1963) that the mortality rate of widowers is particularly high during the first six months of bereavement. Conversely, the suggestion by Cox and Ford (1964) that the mortality of widows is higher than average in the second year of bereavement was, in this survey, found to be not significant at the 10% level and therefore not confirmed.

Close Relatives Excluding Widowed People

Apart from widowed people, there were 747 close relatives in the bereaved group and 712 in the control group. During the first year of bereavement 3.21% of these close relatives died in the survey group compared with 0.56% in the control group. This increase in risk for bereaved relatives was significant at the 0.1% level.

The mortality rates for the bereaved parents, children, and siblings are shown in Tables V and VI. These show an increase in mortality during the first and sometimes the second year of bereavement for each type of relative and that in each case the increase in mortality for the bereaved male relative is greater than for the female relative. The statistical significance of the differences in mortality determined for these various groups is shown in Table VII.

TABLE VII.—Statistical Significance of the Differences in Mortality Recorded During the First Year of Bereavement

	Total	Male	Female
All relatives	0.001	0.01	0.1
Parents	N.S.	N.S.	N.S.
Widowed	0.01	5.0	1.0
Children	5.0	5.0	N.S.
Siblings	5.0	N.S.	N.S.
All relatives (excluding widowed people)	0.1	1.0	N.S.

N.S. denotes that the levels were not found to be statistically significant.

Place of Death

An assessment was made to determine whether the place at which people die is related in any way to the subsequent mortality of close relatives. The various places at which death occurred and the number of deaths which occurred at each site are given in Table VIII. This shows that in this area, though little difficulty is experienced in admitting the old, the chronic sick, and the dying into hospital, a very high proportion of people die at home. Because the place of death is often chosen by the patient, his family, or the people caring for him, the fact that 25.9% of the people without close relatives die at home is noteworthy.

TABLE VIII.—Places at Which People Died

	Home	Hospital	Chronic Sick Unit	Old People's Home	Other Sites	Total
<i>Original Sample</i>						
Male	108	86	24	12	14	244
Female	104	70	57	8	5	244
Total	212	156	81	20	19	488
%	43.4	32.0	16.6	4.1	3.9	100
<i>No Close Relatives</i>						
Male	10	9	12	9	2	41
Female	18	12	29	6	1	67
Total	28	21	41	15	3	108
%	25.9	19.4	38.0	13.9	2.8	100
<i>Those with Close Relatives</i>						
Male	98	78	12	3	12	203
Female	86	57	28	2	4	177
Total	184	135	40	5	16	380
%	48.4	35.6	10.5	1.3	4.2	100

Table IX gives the percentages of people who died each year, at the sites listed, whose death was followed by the death of a close relative. Close relatives of 13 (7.1%) of the 184 people who died at home died within the ensuing year, compared with the relatives of 17 (12.6%) of the 135 people who died in a general hospital and 7 (17.5%) of the 40 people who died in a chronic sick unit. Close relatives of 24 (13.7%) of the 175 people who died in hospital died within the following year. It seems, therefore, that the risk to a bereaved close relative of dying within one year of bereavement is determined, in part, by the place of death of the first relative. If the first relative dies in hospital the bereaved close relatives carry twice the risk of dying within a year of bereavement than if the first relative had died at home. This increase in risk for bereaved close relatives when the original death occurred in hospital compared with at home was significant at the 5% level.

TABLE IX.—Percentages of People Who Died Each Year, At the Sites Listed, Whose Death was Followed by the Death of a Close Relative

	Years of Bereavement					
	-1	-2	-3	-4	-5	-6
Died at home	7.1	5.0	1.2	2.5	0.6	0.6
Died in hospital	12.6	3.7	3.8	4.0	2.0	1.0
Died in chronic sick unit	17.5	9.1	6.7	—	—	—
Died in old people's home	—	—	20.0	—	—	—
Died at other sites	37.5	—	20.0	—	—	—

Similarly, a difference in risk was found to occur when the original death occurred at some site other than at home or hospital. It was found that 19 people died at sites other than hospital or home and that 16 of these people had close relatives living in the area. The "other sites" included roads, fields, a cemetery, chapel, shop, wood, bowling-green, and pond. Deaths at these sites were invariably sudden and the shock to relatives consequently great. Their grief was often increased by the need for a necropsy and inquest. Six (37.5%) of these deaths at other sites were followed within one year by the death of a close relative, and of the close relatives at risk during this period 11.6% (6) died.

Close relatives of 13.7% of the people who died in hospital and of 37.5% of those who died at other sites died within one year of bereavement. This increase in risk for the relatives of people who died at other sites compared with those who died in hospital was significant at the 5% level.

Close relatives of 7.1% of the people who died at home and of 37.5% of those who died at other sites died within one year of bereavement. This increase in risk for the relatives of people who died at other sites compared with those who died at home was significant at the 0.01% level.

Age of Relatives who Die Following Bereavement

The age distribution of all the people resident in the area who died during the six-year period is given in Table II. The mean age of death for this group was 73.35 ± 13.8 . The mean age of those people whose death was followed within one year by the death of a close relative was 70.9 ± 13.2 . The mean age of the relatives who died during the first year of their bereave-

FIG. 2.—Age distribution of relatives who died within one year of bereavement.

ment was slightly lower at 69.75 ± 14.7 . These figures suggest that people who die following bereavement are on average slightly younger than the relatives who predeceased them and that they die at an earlier age than is usual for the community in which they live. Fig. 2 shows the age distribution of relatives who died within one year of bereavement. This chart is biphasic, with two modes, A and B. Histograms (not shown) of the age distribution of all the people who died in the area and of those people whose death was followed within one year by the death of a close relative each have only one mode, and these occur in the same general age distribution as mode B in Fig. 2. The presence of mode A in the chart suggests that a

significant number of relatively young people are particularly at risk during the first year of bereavement.

Summary

A survey was made in a semirural area (pop. 5,184) to determine whether bereavement produced an increased mortality among bereaved close relatives—these being defined as a spouse, a child, a parent, or a sibling. During a six-year survey period 488 residents died; 371 of these people had close relatives living in the survey area, and the subsequent mortality of their 903 close relatives was compared with that of a control group; this control group was composed of the 878 close relatives of 371 people matched by age, sex, and marital state with the people who had originally died.

It was found that 4.76% of bereaved close relatives died within one year of bereavement compared with 0.68% in the control group. This sevenfold increase in risk between the bereaved and control group was significant at the 0.001% level, and indicates that bereavement carries a considerably increased risk of mortality. This risk was found to be greater for male than for female relatives: 6.4% of the 391 male relatives at risk died, compared with 3.5% of 512 female relatives. This difference in risk between the sexes was significant at the 5% level.

The increase in risk was particularly great for widowed people and least for female children. During the first year of bereavement 12.2% of widowed people died, compared with 1.2% in the control group. This increase in risk for widowed people was significant at the 0.01% level. Of the remaining close relatives in the survey group, 3.21% died during the first year of bereavement, compared with 0.56% in the control group. This increase in risk for bereaved close relatives, excluding the widowed, was significant at the 0.1% level.

There is a relation between the place at which a person dies and the subsequent mortality of bereaved relatives. The risk of close relatives dying during the first year of bereavement is doubled when the primary death causing bereavement occurs in a hospital compared with at home. This difference in risk was significant at the 5% level.

If the primary death occurs at some site—for example, a road or field—other than at home or hospital, the risk of a close relative dying during the first year of bereavement is five times the risk carried by the close relatives of people who die at home. This difference in risk was significant at the 0.01% level, though the small size of the sample reduces the significance that can be attributed to the result.

People who die following a bereavement are on average slightly younger than the relatives who predeceased them, and they die at an earlier age than is usual for the community in which they live.

We are grateful to Dr. Felix Richards for providing data used in the survey and to Miss Kathleen Vaughan for her considerable help in identifying the close relatives resident in the area.

Severe Outbreak of Surgical Sepsis Due to *Staphylococcus aureus* of Unusual Type and Origin

RICHARD W. PAYNE,* M.A., M.D., M.C.PATH.

Brit. med. j., 1967, 4, 17-20

Outbreaks of staphylococcal infection in hospital due to infection arising in the operating-theatre are probably less rare than reports in the literature would suggest. There are many possible explanations for this natural reticence. However, it is felt that the following outbreak should be recorded since there are a number of features of general interest.

Outbreak in Outline

The outbreak occurred at St. Albans City Hospital—a 400-bedded provincial general hospital—in January 1963. Each surgical ward has for some years maintained a wound infection register and it has been the practice of the clinical pathology department to keep a record of all coagulase-positive staphylococci (*Staphylococcus aureus*) isolated from patients in the hospital; a record is also kept of the antibiotic sensitivity pattern of each organism. In January 1963 the number of patients from whom *Staph. aureus* was isolated began to rise (Fig. 1). Nearly all these organisms were resistant to penicillin, streptomycin, and tetracycline when tested by a routine Multidisk diffusion method. This was a pattern of antibiotic resistance that was uncommon in the hospital at the time.

FIG. 1.—Weekly number of patients with *Staph. aureus* infections in January and February 1963.

Early in the outbreak it became apparent that all the affected patients had staphylococcal wound infections and that patients in many separate wards were involved. The patients were under the care of six consultant surgeons. It was therefore felt that the most probable source of infection lay in the operating-theatres.

Subsequently, *Staph. aureus* was shown to be widely distributed throughout the theatre suite. It was also found that an anaesthetist (A) was not only a nasal and skin carrier but also a "disseminator" of *Staph. aureus* of the same antibiotic-sensitivity pattern as the affected patients.

* Consultant Clinical Pathologist, Mid-Herts Group of Hospitals. Present address, Department of Haematology, The Victoria Infirmary, Glasgow S.2

The theatres were closed and washed down with hypochlorite solution. This was not effective, so the theatre suite was washed down again much more thoroughly with hypochlorite solution followed by fumigation with formalin vapour and finally shown to be bacteriologically clean.

Organism

Coagulase-positive staphylococci (*Staph. aureus*) of two phage patterns were involved in this outbreak: (a) phage type 80 and (b) phage untypable (Holt, 1963). The antibiotic sensitivity patterns of these two different phage types of *Staph. aureus* were the same, as shown by a Multidisk plate diffusion method (Table I).

TABLE I.—Results of Antibiotic Sensitivity Tests (Disc Diffusion Method)

Antibiotic	Amount in Disc	Sensitive (S) Resistant (R)
Ampicillin	10 µg.	R
Chloramphenicol	10 "	S
Erythromycin	10 "	S
Methicillin	10 "	S
Neomycin	10 "	S
Novobiocin	5 "	S
Penicillin	1.5 "	R
Phenethicillin	1.5 units	R
Cloxacillin	5 µg.	S
Streptomycin	10 "	R
Sulphafurazole	100 "	R
Tetracycline	10 "	R

The phage "untypable" strain was further investigated in the Department of Bacteriology at the Leeds School of Medicine. Their report stated "This strain is typical of our yellow isolates. It forms bright yellow pigment on glycerol monoacetate agar, is non-proteolytic, and multiple-resistant (resistant to penicillin, streptomycin, tetracycline, and mercury). It falls into phage group III, subdivision 77w (1,000 R.T.D.)" (Jacobs, Willis, Ludlam, and Goodburn, 1963; Willis, 1963).

Carrier

Swabs taken from the anterior nares, the dorsum of each hand, and the forehead of the anaesthetist (A.) on 24 January all yielded a heavy growth of *Staph. aureus*. The organisms had the same antibiotic sensitivity pattern as those isolated from the affected patients (Table I) and were subsequently shown to be of the same phage patterns (phage type 80 and phage untypable).

In retrospect it was discovered that A. had been found to be a nasal carrier of *Staph. aureus* three years previously at another hospital. During the ensuing three years he had been actively associated with clinical work in other hospitals, but had not to his knowledge been associated with an outbreak of staphylococcal infection previously. He had had psoriasis for eight years. In December 1962 he had suffered an acute exacerbation of his skin condition necessitating hospital admission and local and systemic treatment with corticosteroids. This acute exacerbation had settled fairly rapidly, leaving many

large desquamating but not overtly infected areas of skin. A. returned to his anaesthetic duties on 7 January 1963 and continued to work until 24 January.

Exposure plates were placed on the floor of a room for 20 minutes prior to A.'s entry and then for 20 minutes, during which time A. entered the room, removed his clothes, and dressed again at a distance of 10 feet (3 metres) from the plates. The plates exposed while A. undressed and dressed showed a heavy contamination with *Staph. aureus* (Fig. 2) of the two phage patterns, described above.

FIG. 2.—Twenty-minute exposure plates (blood-agar) taken (a) before A.'s entry into room and (b) after A.'s dressing and undressing in room.

Theatre Suite

The theatre suite is modern, having been in use since November 1959. There is a plenum system of ventilation, with adiabatic cooling and humidification, which gives about 17 changes of air per hour in the theatres. Exposure plates placed at seven sites in the theatres and also swabs taken direct from six random sites showed the widespread presence of *Staph.*

TABLE II.—Sites of Origin and Phage Types of *Staph. aureus*

Source	Total	Phage Untypable	Phage Type 80	% Phage Untypable

Pneumonia	5	5	0	100
Peritonitis	2	2	0	100
Deaths:				
Pneumonia 2, peri-				
tonitis 2	4	4	0	100

aureus. The total colony counts on these exposure plates varied from 10 to 28 colonies per plate per hour of exposure (mean 17 colonies per plate per hour) and a total of six colonies of *Staph. aureus* were isolated (5% of total colonies isolated). *Staph. aureus* was also isolated from swabs taken direct from three of the six random sites. These organisms were of the same antibiotic sensitivity patterns and same phage type as those isolated from the carrier (Table II). No staphylococci were isolated from the filters or air-ducts of the ventilating plant.

Patients

A total of 33 patients were involved in this outbreak; in all of them surgical wounds were the primary site of infection. *Staph. aureus* phage type 80 was isolated from wound swabs from 4 of the patients, while the phage-untypable strain was isolated from the other 29 patients' wound swabs (Table II). The patients' ages ranged from 8 months to 88 years; 15 were male and 18 female.

Patients in 11 wards and under the care of six surgeons were involved in this outbreak. The distribution of patients according to wards and to surgical teams is given in Tables III and IV respectively.

TABLE III.—Distribution of Patients with Staphylococcal Wound-sepsis by Wards

Ward	No. of Cases
Male surgical 1	8
" 2	6
Female " 1	6
" 2	3
Gynaecological	4
6 other wards (1 case in each)	6
Total	33

TABLE IV.—Distribution of 33 Patients with Staphylococcal Wound-sepsis by Surgical Teams

Surgeon	Specialty	No. of Cases
A	General surgery	11
B	"	6
C	Orthopaedics	6
D	Obstetrics and gynaecology	5
E	General surgery	3
F	"	2

All the patients were operated on in the theatres in the operating-suite described above during the period 9–28 January. Thirteen were operated on in theatre 1 and twenty in theatre 2. These details are summarized in Table V, together with the total number of operations performed in each theatre during the above period. Out of a total of 217 patients operated on 33 (15.2%) developed staphylococcal wound infections.

TABLE V.—Distribution of Patients with Staphylococcal Wound-sepsis by Operating-theatre

	No. of Infected Cases	Total No. of Operations	% Wound Infections
Theatre 1	20	115	17.4
" 2	13	102	12.7
Total	33	217	15.2

The interval between the time of operation and of clinical presentation of wound infection ranged from 2 to 20 days (mean 9.6 days) (Fig. 3).

In Fig. 4 an attempt has been made to correlate the subsequent occurrence of wound sepsis in a patient with A.'s presence in the theatre at the time of the operation. Staphylococcal wound infections continued to occur for five days after A.'s last attendance in the theatre suite and for 10 days after his last known attendance in theatre 2.

Complications

In addition to wound sepsis and its surgical sequelae staphylococcal pneumonia occurred in five patients, and staphylococcal peritonitis in two. All of them were infected with the phage-untypable strain of *Staph. aureus* (Table II).

Mortality

In spite of intensive treatment there were 4 deaths among the 33 patients (mortality rate 12.1%). These deaths occurred in patients in whom complications had developed—two had

FIG. 3.—Time interval between operation and isolation of *Staph. aureus* from wound swabs. FIG. 4.—Retrospective analysis of the carrier's presence or absence in the theatre at time of operation.

developed pneumonia and two peritonitis, due in all cases to the phage-untypable strain of *Staph. aureus* (Table II).

Management

On 24 January it became apparent that the theatre suite was contaminated with *Staph. aureus* and that the most likely source of these organisms was the anaesthetist, A. At the time it was decided, firstly, to suspend A. from duty; secondly, to close and cleanse the theatre suite (using another operating theatre for emergency surgery); thirdly, to suspend elective surgery; and, fourthly, to regard any ward in which a patient had developed a staphylococcal wound infection as contaminated.

The theatre suite was closed on 24 January and washed down with 1:80 sodium hypochlorite solution. The theatres were reopened after 36 hours, but subsequently it was discovered that staphylococci were still present. The suite was therefore closed again, and every part (including ceilings, cupboards, and loose apparatus) was scrupulously washed with 1:80 sodium hypochlorite solution by hand, while all dressings and linen were laundered and autoclaved. Finally, the whole theatre suite was fumigated with formalin vapour produced from the Formitas outfit (Sanitas & Co. Ltd.) and kept sealed for four hours; during this procedure the ventilating plant was stopped. Twenty-four hours later no staphylococci were isolated on prolonged (12-hour) exposure plates or direct swabs taken at many sites in the theatres.

Because of the large number of patients affected in this outbreak, the normal facilities for isolation soon became inadequate. Therefore it was decided to segregate infected and non-infected patients in separate "dirty" and "clean" wards respectively. As soon as a patient was discharged from a "dirty" ward, his bedding and surrounding curtains were "formalin-stoved" and laundered. After the last patient had been discharged each "dirty" ward was cleaned in the same careful way as in the theatres on the second occasion (washing down with a 1:80 solution of sodium hypochlorite, followed by formalin fumigation).

Discussion

Different strains of *Staph. aureus* show wide variation in virulence (Barber, Dutton, Beard, Elmes, and Williams, 1960). In particular, phage type 80/81, first isolated in Australia by Rountree and Freeman (1955) has subsequently been associated with severe outbreaks of staphylococcal infection throughout the world. More recently a newly recognized strain of *Staph. aureus*, designated phage type A, has been associated with a series of severe staphylococcal outbreaks in six hospitals in the Glasgow area (Temple and Blackburn, 1963) and also in hospitals in the Leeds area (Jacobs, *et al.*, 1963). In the present outbreak, 4 cases were associated with phage type 80 infections

and 29 with the phage-untypable strain. This untypable strain was isolated from all the patients in whom staphylococcal pneumonia or peritonitis occurred. This may imply that the untypable strain was more virulent or more infective to patients than phage type 80 (it is of interest that the observed incidence of both strains in the theatre was almost equal). It is therefore felt that attention should be drawn to the occurrence of the outbreak, though it is impossible to foretell the future importance of this strain.

In the outbreak under review circumstantial evidence strongly suggests that the patients' wounds became infected in the theatre at the time of the operation. Other workers have also concluded that suppuration in surgical wounds is most likely to have arisen from infection in the theatre (Gillespie, Alder, Ayliffe, Bradbeer, and Wypkema, 1959; Howe and Marston, 1962). An anaesthetist (A.) appears to have been the source of staphylococcal contamination of the theatre suite. It is of interest to note that this individual had in the past been a nasal staphylococcal carrier, and had had psoriasis which remained quiescent until December 1962, when he suffered an acute exacerbation of his skin condition. However, at the time of his return to duty, in January 1963, his skin was desquamating over wide areas. The increased liability of patients with certain skin lesions to be disseminators of staphylococci has been demonstrated by Hare and Cooke (1961), while Davies and Noble (1962) have demonstrated the importance of desquamated skin-scales in the carriage of bacteria. It is possible that A. was transformed from a relatively harmless nasal carrier into a highly dangerous staphylococcal disseminator by the presence of desquamating psoriatic lesions colonized by staphylococci. In this context the part played by topical and systemic corticosteroid therapy on the change in A.'s skin: bacteria relationship remains unknown.

It was not possible to determine the aerial density of staphylococci in the theatre suite during this outbreak, but an impression of the numbers of organisms disseminated by A. has been given in Fig. 2. Wound infections continued to develop in patients operated on during the five days after A.'s last attendance in the theatre suite, the most probable explanation being the continued survival of staphylococci in the theatres, for Noble

(1962) has shown that these organisms can survive for up to seven days in ward air. Though it has been shown that efficient theatre ventilation will greatly reduce the concentration of air-borne bacteria (Shooter and Williams, 1961) it is quite apparent that modern plenum ventilation was unable to prevent theatre infection in these circumstances.

Considerable doubt has been cast on the value of "routine" washing down of theatres with 1:80 sodium hypochlorite solution, since it has been shown that staphylococci survived this procedure during the first closure of the theatre suite. However, the combined use of the same strength of hypochlorite solution applied to literally every part of the theatre suite and its contents, followed by formalin fumigation, has been shown to have been effective, since staphylococci could no longer be isolated and no further wound infections occurred. It is not possible to define the relative importance of the thorough washing down with hypochlorite solution in relation to the importance of formalin fumigation. Hare, Raik, and Gash (1963) have, however, shown under experimental conditions that 1:80 sodium hypochlorite solution was highly efficient in killing *Staph. aureus* whereas formalin was much less effective. The dangers of relying on "routine" cleansing of contaminated theatres have been inadvertently demonstrated in this outbreak, and it is my view that such theatres must remain out of use until full bacteriological results are available.

The policy of segregation of patients into "clean" and "dirty" wards in an outbreak of this type appears to have been justified, since no obvious cases of cross-infection in the wards were detected. This, in addition, reflects great credit on the nursing staff.

Noble (1962) found six disseminators of staphylococci in 3,675 surgical patients. The incidence of disseminators among those working in operating-theatres is not known, but the outbreak under review emphasizes the grave hazards of the presence of such an individual in the theatre.

The *Lancet* (1963) stated: "Without dependable statistics it is impossible to assess the size of the staphylococcal problem or to determine the value of control measures. . . . The detection and recording of *all* infections, trivial and serious, the identification of important sources of cross-infection, the correlation of clinical and laboratory findings, and the supervision of special precautions all take more time than can be spared by busy doctors and nurses." From personal experience I would wholeheartedly support these views, for during this outbreak it was impossible to attend to any other duties or commitments. It is felt that the suggestion, made by Gardner, Stamp, Bowgen, and Moore (1962) and quoted in the same *Lancet* editorial, of overcoming these difficulties by appointing a full-time sister to work with the team in control of infection is one that should be carefully considered by many hospitals.

Considering this outbreak in retrospect it is felt that three points, which though obvious are nevertheless of fundamental importance, should be stressed: (1) the value of keeping a central register of *all* staphylococcal infections occurring in a

hospital; (2) the importance of the co-operation of the medical staff in formulating a comprehensive collective plan of action at the earliest possible stage; and (3) the importance of the co-operation of medical, nursing, and administrative staffs in rapidly implementing this plan.

Summary

A severe outbreak of staphylococcal infection involving 33 surgical patients in a general hospital is described.

Two strains of *Staphylococcus aureus* were involved: phage type 80 (4 cases, no deaths) and phage untypable (77w (1,000 R.T.D.)) (29 cases, 4 deaths).

An anaesthetist suffering from psoriasis was found to be carrying and disseminating staphylococci of these two strains, which were found to be widely distributed in two operating-theatres.

The findings, and the management of the outbreak, are described and discussed.

ADDENDUM.—Since this paper was submitted for publication a similar but smaller outbreak of surgical wound infection has been reported by Ayliffe and Collins (G. A. J. Ayliffe and B. J. Collins, *J. clin. Path.*, 1967, 20, 195). These infections were probably also acquired in the operating-theatre, from an orderly who had generalized dry eczema and who was both a nasal and skin carrier and a disseminator of another unusual strain of *Staph. aureus*.

I am greatly indebted to all who were involved in investigating and controlling this outbreak, whether medical, nursing, laboratory, or administrative staff. I also wish to thank Drs. Holt, Jacobs, and Willis for permission to quote the results of their investigations.

Glucose Tolerance and Serum Insulin in Unaffected Identical Twins of Diabetics

D. A. PYKE,* M.D., F.R.C.P.; K. W. TAYLOR,* M.A., PH.D., M.B., B.CHIR.

Brit. med. J., 1967, 4, 21-22

Since diabetes mellitus is partly inherited a study of the unaffected identical twin of a diabetic may yield useful information regarding both its genetics and its metabolic abnormalities.

About half of the pairs of identical twins so far reported have been concordant—that is, both twins were diabetic (Joslin *et al.*, 1959; Harvald and Hauge, 1963). If diabetes is transmitted by a single gene then all the twins ought eventually to become diabetic, unless “penetrance” is incomplete. Glucose-tolerance tests may reveal abnormalities in such apparently unaffected twins.

In addition the insulin response to glucose of a series of twins of diabetics has not so far been reported. Such studies might reveal whether these apparently normal twins show antagonism to insulin or impairment of the response of the beta cell to glucose. Thus increased blood insulin levels with normal glucose tolerance might indicate antagonism to insulin, and lower levels after glucose might reflect a diminished insulin secretion.

We report here the results of glucose-tolerance tests performed on nine apparently healthy identical twins of diabetics. Blood insulin was determined during the tolerance tests.

Present Investigation

Subjects.—The clinical characteristics of the twins are shown in Table I. In six cases the twins were female and in three male. The age at diagnosis of diabetes in the affected twin varied from 5 to 52; in all but two it was under 45 years. The mean interval from diagnosis in the affected twin to the time of testing the unaffected twin was five years. In pair 3 both twins were fat (50% overweight), but in the other pairs neither the diabetic nor the non-diabetic twin was significantly overweight—that is, none was 10% overweight. In seven of the nine pairs there was a family history of diabetes; in pair 2 both parents were diabetic.

TABLE I.—Clinical Details of Identical Twins Studied

Pair No.	Sex	Age at Test	Age at Diagnosis of Diabetes in Affected Twin	Familial Relationship with Other Members of Family with Diabetes
1	F	23	13	Grandfather, 2 great aunts, 1 uncle. (All maternal)
2	M	55	52	Mother. Father. Daughter
3	M	55	50	Father
4	F	23	20	None
5	M	30	28	Uncle
6	F	43	43	Mother
7	F	43	43	Sister
8	F	56	44	Great aunt.
9	F	14	5	Great uncle (maternal)

Normal Persons.—The normal group for comparison of serum insulins consisted of 24 individuals (8 male, 16 female) aged between 18 and 75. None of the normals differed from their expected weight by more than 10% and none was known to have a family history.

Procedure.—In some cases the tests were done at King's College Hospital, and in others one of us carried out the test

* Diabetic Department and Department of Medicine, King's College Hospital, London S.E.5.

in the patient's home. All subjects took a full carbohydrate diet for at least three days before the test. Venous blood was taken from a forearm vein after an overnight fast. Then 50 g. of glucose was given by mouth, and blood samples were taken 30, 60, and 120 minutes later. Determinations were made of glucose and insulin. For determination of insulin the blood was allowed to clot and the serum was separated by centrifugation. Serum was stored at -20°C . Insulin was measured by immunoassay; Hales and Randle's (1963) method being used with certain modifications, the most important being the use of 0.01 M disodium diethyltetracetic acid in the reaction mixture (Morgan *et al.*, 1964; Sheldon and Taylor, 1965), to avoid interference from complement. Results on human serum were compared with the response to ox insulin standards prepared from a recrystallized specimen kindly provided by Wellcome Laboratories, Beckenham, Kent. Glucose was determined by an oxidase method (Huggett and Nixon, 1957).

Confirmation that twins were identical was obtained by determining blood groups ABO, MN, S, P, Lu^a, Le^a, Le^b, Fy^a (through the kind help of the Blood Group Reference Laboratory, Lister Institute).

Results

Normal Persons.—Blood glucose and serum insulin levels in normal persons are shown in Table II. These results do not show marked differences from those of many other workers who have employed a test of this type. The blood glucose results, for example, are very slightly lower than those of Welborn *et al.* (1966) for 45 normal volunteers in whom blood glucose was determined by a ferricyanide method after 50 g. of oral glucose. Serum insulin values obtained by various

* Thirty-four normal individuals were tested for glucose tolerance and 25 for serum insulin.

immunoassay methods which differ considerably in detail have been remarkably uniform from one group of workers to another (see Taylor, 1967). Moreover, our results in normal subjects differ only slightly from values in an earlier series obtained in 10 normal people in this department (Rudnick and Taylor, 1965). As has been noticed by Welborn *et al.* (1966) serum insulin levels did not differ with age.

Twins.—Serum insulin and blood glucose values in the nine twins of diabetics are shown in Table II. It will be seen that

P25567

glucose tolerance is abnormal by comparison with the control group. Blood glucose levels are significantly different in the twins from those in the controls in the fasting state and after glucose. In only two curves did all the points lie within two standard deviations of normal values. The others showed high values, especially one and two hours after glucose. The two subjects with normal glucose tolerance results were from the only pairs without a family history of diabetes. Serum insulin levels in the fasting state did not differ between the groups. However, insulin levels were lower than normal half an hour and one hour after glucose in the twins.

Discussion

The significance of these abnormal blood glucose levels is increased by the fact that the subjects are young. High blood glucose values after oral glucose are rare in early life (Butterfield, 1964). Despite these high blood glucose levels serum insulin levels are low, particularly after glucose.

There are a number of possible explanations for this reduced response to glucose. It might be that not all the insulin in the blood is being measured. At present there is no conclusive evidence to suggest that immunological methods fail to measure all the available insulin in the blood. When attempts are made to extract insulin from blood proteins by various acid-ethanol methods there does not appear to be any release of insulin previously associated with other proteins (Karam *et al.*, 1963). When higher values for blood insulins have been obtained by bioassay methods their significance is doubtful. It has always been difficult to measure blood insulin levels with precision by the rat diaphragm technique (Taylor and Randle, 1959), and the biological significance of adipose tissue assays for blood insulin is uncertain (Kipnis and Stein, 1964; Rasio *et al.*, 1965).

It might be that insulin was being more rapidly broken down in the twins of diabetics. However, serum insulin levels tend to rise after glucose less than in normal persons, though fasting levels are not different in the two groups. This is not the pattern of response which would be expected if there were a uniformly enhanced rate of insulin destruction throughout the glucose-tolerance test. Neither do these studies give any evi-

dence of antagonism to endogenous insulin, which would lead to raised levels of blood insulin in the presence of a normal glucose tolerance. It seems much more likely that the response of the beta cell to a rise of glucose concentration is less than normal. The diminished glucose tolerance of some of these non-diabetic twins may be a consequence of diminished insulin response to oral glucose.

The clinical significance of these findings is not known. In particular, we do not know whether the abnormalities will progress to frank clinical diabetes. We intend to observe the present group and collect data on other identical twins of diabetics.

Summary

Glucose tolerance and serum insulin levels have been examined in nine apparently normal twins of diabetics and compared with the results in normal people.

Mean glucose tolerance was significantly less than that of normals and serum insulin levels after sugar were also low.

It is suggested that the impairment of glucose tolerance in some of these twins is a consequence of a diminished response of the beta cell to glucose.

Glucose Tolerance and Serum Insulin in the Unaffected First-degree Relatives of Diabetics

K. W. TAYLOR,* M.A., PH.D., M.B., B.CHIR.; JOANNA SHELDON,* M.D., M.R.C.P.; D. A. PYKE,* M.D., F.R.C.P.
W. G. OAKLEY,* M.D., F.R.C.P.

Brit. med. J., 1967, 4, 22-24

In the preceding paper the effects of oral glucose on blood glucose and serum insulin levels were examined in the identical twins of known diabetics, and abnormalities of glucose tolerance and serum insulin levels in some of them were shown. It seemed of interest to determine whether these abnormalities were present in other first-degree relatives of diabetic patients. In addition, serum insulin and glucose tolerance were examined in a small group of relatives of diabetic patients who gave clinical evidence of hypoglycaemia.

Methods and Subjects

Blood glucose and serum insulin were measured by methods identical to those in the preceding paper. The results have been compared with the same control series.

Six children of conjugal diabetic couples were studied and studies were made of a family of nine children derived from an additional conjugal pair of diabetics.

Nine other first-degree relatives of diabetics were studied. None of them was previously known to have diabetes. As in the preceding paper, subjects were tested after an overnight fast and after at least three days on a normal carbohydrate diet. All but one of these patients were aged under 45.

spring of conjugal diabetics blood glucose values were somewhat higher than those obtained in the control series (Table I). This is particularly noticeable half to one hour after glucose. By contrast, serum insulin levels in the offspring of the conjugal group were similar to those obtained in the normal series. A similar pattern of insulin and glucose is observable in the other first degree relatives tested. In the instance where the subject was obese (Case 11) rather high serum insulin values were obtained. This result is in line with other observations which suggest that elevated blood insulin levels are characteristic of obesity whether diabetes is present or not (Karam *et al.*, 1963). Studies were also made on nine offspring of a single pair of conjugal diabetics. Values for blood glucose and serum insulin are shown in Table II. One subject (E) was

insulins were usually increased at those times. These values were significantly greater than those in normal people.

Discussion

These results (like those in the preceding paper) suggest that glucose tolerance is often abnormal in the close relatives of diabetic patients. This is so in all the groups tested, but is especially noticeable in the nine children of a single conjugal pair of diabetics. There have so far been few studies of glucose tolerance in large families. Fajans (1964) has drawn attention to some similar results obtained by glucose-tolerance tests in another family study. Thus when 10 apparently healthy children of a diabetic father were tested seven were found to be diabetic.

Despite the abnormal levels of blood glucose recorded in this paper (with the exception of those with hypoglycaemia) blood insulin values have been relatively low. These values confirm those obtained by a number of other workers who have found normal or reduced levels of blood insulin in close relatives of diabetics (Grodsky *et al.*, 1965; Colwell and Lein, 1966). The insulin response to intravenous glucose has also been reported to be reduced (Cerasi and Luft, 1963) or normal (Soeldner *et al.*, 1966) in a number of relatives of diabetic patients. There now seems to be general agreement among workers who have used various types of immunological techniques for measuring insulin that blood insulin levels are relatively low in the relatives of diabetics.

A different type of response had earlier been found by Steinke *et al.* (1963), who used an adipose-tissue method to measure insulin in the blood of a large group of the offspring of conjugal diabetics. Increased insulin-like activity was found in the serum of many, though not all, such subjects. The authors were careful to point out that the physiological significance of blood-insulin activity measured in this way is uncertain.

The results shown both in this paper and in the preceding one suggest that in close relatives of diabetics there may be an impairment in the response of the islet cells to glucose. It is at present not known whether this defective response extends to other stimuli for insulin secretion such as amino-acids, glucagon, or sulphonylureas. If it is a defective response only to sugars that is being measured, then the defect could lie either with the phosphorylation of glucose, within the beta cell or in

found to be frankly diabetic, and abnormalities of glucose tolerance were discovered in several of the other offspring. Again serum insulins were relatively low, apart from one patient (F) who showed an extreme rise after glucose. The pattern of serum insulin response after glucose is characterized by a normal fasting level and slow rise in insulin, suggestive of a delayed and inadequate response of the beta cells to stimulation by sugars.

Blood Insulin and Glucose in Patients with a Clinical History of Hypoglycaemia.—Glucose-tolerance tests were carried out and serum insulin values were measured in four patients with symptoms of hypoglycaemia, all with first-degree relatives with diabetes. Results are shown in Table III. Relatively low blood sugars were obtained two hours after taking glucose, though values at 30 and 60 minutes were high, and serum

worker in a previous study of 80 healthy subjects (40 males, 40 females)—mean percentage adhesive platelets 40.3, standard error ± 0.9). For the purpose of this study, therefore, these group 1 patients have been regarded as controls, and differences in means have been analysed against them.

Those subjects found to have benign tumours (group 2) did not differ in their mean adhesiveness from those in group 1, though the mean initial platelet count in this group was significantly lower than in the others. In patients with invasive

patients could account for the variation in platelet adhesiveness shown. There appears to be no explanation for the low mean initial platelet count in the group of patients with benign tumours, but the number in this group was small.

Nathanson and Savitsky attributed the increased platelet stickiness found in patients with cerebral tumours to a non-specific effect of malignancy. Yet the occurrence of similar changes in platelet adhesiveness in patients with active multiple sclerosis and rapidly growing brain tumours suggests an alter-

Platelet Stickiness in Intracranial Tumours

	Group 1	Group 2	Group 3	Group 4
No.	15	9	10	18

Mean % adhesive platelets	39.8 $\pm$ 1.8	39.9 $\pm$ 2.6	41.5 $\pm$ 2.7	49.4 $\pm$ 2.0 (P < 0.01)

Standard errors follow $\pm$ sign.

P values are given where means differ significantly from those in Group 1.

Group 1: No space-occupying lesion found. Group 2: Benign tumours. Group 3: Invasive tumours; clinical history of more than three months' duration. Group 4: Invasive tumours; clinical history of three months or less.

tumours platelet stickiness was increased. The increase was small and did not reach significance in those with a longer clinical history (group 3), but became more striking and was significant in group 4 patients with a presenting history of three months' duration or less (P < 0.01). The mean age for this group was, however, significantly higher than that of the control patients (P < 0.05).

The mean percentage of adhesive platelets did not differ significantly between patients with cerebral metastases and those with primary brain tumours.

Discussion

These findings support Nathanson and Savitsky's (1952) observation that platelet adhesiveness is increased in brain tumours. In this larger series raised stickiness was found to occur most often in those patients with invasive tumours and a short history of disease, while platelet adhesiveness in patients with benign tumours lay within the normal range. It is recognized that the length of a patient's history may be influenced by many factors, but in general most rapidly growing brain tumours cause the patient to present for investigation within a few weeks of the onset of symptoms, and it is these tumours which are associated with a relatively rapid destruction of neural tissue.

The group of patients showing increased platelet adhesiveness while matched for sex were significantly older than the control patients with negative investigations. However, the effect of age upon platelet adhesiveness is not yet clear. In a previous study (Millac, 1967b) no significant effect of age, within a similar range, on adhesiveness was found in 80 healthy subjects and 82 patients with multiple sclerosis. It is thought unlikely that the difference in age between these two groups of

native explanation. In both these clinical situations there is acute destruction of neural tissue, and it seems possible that degradation products may enter the circulation and bring about the alteration in platelet behaviour.

Summary

Platelet adhesiveness has been measured in 52 patients admitted with suspected brain tumours. Compared with those patients whose investigations turned out to be negative or in whom the neurological diagnosis was other than brain tumour, patients with invasive tumours and a clinical history of three months' duration or less had a significantly increased platelet adhesiveness. In view of the similarity in alterations of platelet adhesiveness in patients with rapidly growing brain tumours and multiple sclerosis it is suggested that these platelet changes are consequent on acute degradation of neural tissue.

I wish to thank Professor Henry Miller and the physicians and surgeons of the Regional Neurological Centre, Newcastle upon Tyne, for permission to study patients under their care.

Impedance Spirometry in Clinical Monitoring*

J. V. FARMAN,† M.B., F.F.A.R.C.S.; D. A. JUETT,† B.Sc.

Brit. med. J., 1967, 4, 27-29

There are certain places, such as the operating-theatre and the intensive therapy unit, where it is impossible to keep a finger always on a patient's pulse or a constant watch on his breathing. In these circumstances it is customary to employ various types of monitor. Ideally, by using such a machine, one should be able to tell at a glance that the patient is breathing and his heart is beating, even if he cannot be directly observed. Most of the apparatus in common use falls short of this ideal. We have therefore been examining changes in the electrical impedance across the chest as a method of monitoring patients.

Methods of Respiratory Monitoring

Many methods of respiratory monitoring have been employed. The anaesthetic reservoir bag gives a useful qualitative indication of spontaneous respiration, but it cannot be calibrated and it is in any case seldom used in the artificially ventilated patient. Thermistors and pressure transducers placed in the airway also give an indirect indication of respiration. Some mechanical ventilators have calibration marks which purport to measure the tidal volume; these tend to be inaccurate, difficult to read, and in any case capable only of measuring the volume leaving the machine. Only the spirometer and the pneumotachograph can measure accurately the volume of respiration. All these methods share the disadvantage of being placed in the airway, where they will fail to detect disconnection of a ventilator, if this is of the type which continues to function in the presence of a leak. The external strain-gauge pneumograph lacks this drawback but it tends to slip and has not proved popular. Pressure transducers placed in the oesophagus give an even less direct indication of respiration.

For the heart beat the E.C.G. is the best way of detecting arrhythmias and disturbances of conduction, but it is capable of giving a fairly normal-looking trace in the absence of any significant forward flow of blood. Peripheral pulse monitors, apart from their tendency to produce artifacts, err in the other direction by indicating no-flow under conditions of skin vasoconstriction when the cardiac output may be little disturbed.

In any event it is undesirable to have a multiplicity of monitors attached to a patient. They can be such a nuisance to the medical and nursing staff that they may not be used in situations where they might otherwise be helpful. The time needed to apply and adjust them may be too long to be acceptable, particularly in the theatre or recovery room. A variety of leads and transducers attached to the chest and arms may cause dangerous confusion to the attendants and alarm to the patient.

A less obvious disadvantage of many currently available monitors lies in the way in which the information is displayed. Dial displays are difficult to understand if they show rapidly changing variables such as respiration or the arterial pulse, and for this reason the information they impart can only be

of a qualitative nature. In such a case a blinking light will often be more appropriate. Pen recorders are essential for the proper interpretation of the E.C.G., the pneumotachograph, and spiograms, but it is inconvenient and expensive to use them for continuous display purposes at any useful paper speed. For this reason an oscilloscope is best for continuous monitoring purposes. Most oscilloscopes used for this purpose have screens of 3-5 in. (7.5-12.5 cm.) diameter and are far too small to be seen at any distance.

We believe that for any method of monitoring the form of display must be appropriate to the information displayed. Rapidly changing variables should be appreciated as they occur, and for this reason an oscilloscope or a chart recorder is needed to show individual waves. For less rapidly changing variables, such as respiration rate, heart rate, or mean arterial pressure, a meter or digital display is more appropriate. For slowly changing variables such as body temperature a meter can also be used. In addition to this the display should be easily visible from a distance—for example, from across the patient's bed—particularly in the case of the most rapidly changing variables. Lastly, we feel it is important that the criteria which are monitored should be easy to comprehend. This is important when the monitor is to be watched by nurses who may not, for example, understand the significance of changes in rather indirect measurement such as the digital pulse wave.

Impedance Spirometer

Atzler (1935) attempted to measure cardiac activity by following changes in electrical impedance across the chest. He noted at the same time that the transthoracic impedance varied with respiration. Other workers later attempted to record respiration by this means, but modern interest in the method is due largely to the work of Geddes *et al.* (1962b). They passed a small high-frequency current through the chest and were able to demonstrate the relation between changes in the volume of air breathed and changes in electrical impedance. Later work (Kubicek *et al.*, 1964; Pallet and Scopes, 1965; Baker *et al.*, 1965) confirmed that, though the calibration varied, this relation was more or less linear. The slope of the line varied between individuals and depended, moreover, on the position of the skin electrodes, the frequency of the current applied, and the posture of the subject.

Most writers have noted small variations in the tracing synchronous with the heart beat. While this has generally been treated as an artifact we regard it as indicative of pulsatile changes in the volume of blood in the thorax. It is not necessary to assume that this variation is due to change in the size of the heart during each beat. Kubicek *et al.* (1966) concluded that it was probably due to the pulsating pulmonary blood flow. In some of our subjects, however, complex wave-forms have been observed which might be due to changes in heart size (see Fig. 2).

Geddes *et al.* (1962a) showed that it was possible, by the employment of suitable filtering circuits, to record the electrocardiogram from the electrodes used to measure transthoracic impedance. We therefore employ this technique in order to display the E.C.G. at the same time as impedance changes.

* This work was supported by a grant from the Joint Research Committee, United Cambridge Hospitals and East Anglian Regional Hospital Board.

† Addenbrooke's Hospital, Cambridge.

The apparatus we are using consists of a 100 kc./s. oscillator that supplies a constant current of 200 μ A to two electrodes attached to the chest wall. The signals across these electrodes are separated into E.C.G. and 100 kc./s. components. The E.C.G. is fed to a conventional display system and the 100 kc./s. is amplified and rectified to d.c. and then subtracted from a reference potential to give the respiration signal required. We have found it preferable to employ three skin electrodes for long-term monitoring because the addition of an indifferent electrode considerably reduces artifacts on impedance and E.C.G. displays caused by contact with the patient. The electrodes are stainless-steel discs of 2.3 cm. diameter coated with Cambridge electrode jelly. They are attached to the skin by adhesive paper tape.

The outputs of the impedance spirometer and E.C.G. amplifier are displayed on a large screen oscilloscope (Lan Electronics L S 19). The tracings may also be recorded on magnetic tape or on a paper chart recorder. The impedance trace appears as a line of small waves, due to the heart beat, with larger waves due to respiration superimposed (see Figs. 2-6).

Clinical Use

For monitoring purposes the measuring electrodes are attached to the patient's chest at the level of the sixth rib in the mid-axillary line (Fig. 1). At this level the maximum impedance change is seen during respiration (Geddes *et al.*, 1962). The indifferent electrode is placed on the manubrium sterni. Use of a standard arrangement makes it easy for nurses to remember the position. It also allows the conscious patient a good deal of freedom of movement, and, perhaps more important, he is not aware of the presence of the electrodes once they have been applied. The electrodes can be

FIG. 1.—Position of electrodes on patient's chest. The measuring electrodes are in the mid-axillary line and the indifferent electrode on the manubrium sterni.

applied quickly without too much disturbance of the patient. We have found that they can be left on for up to a week without causing irritation to the skin. However, we have experienced difficulty in keeping them attached to the skin in very obese subjects and are at present considering alternatives.

After a few minutes the tracing settles down to the pattern shown in Figs. 2-6. Baseline stability is good so long as the patient remains still. Movement and postural changes, such as lying on one side, alter

the basal impedance, but the baseline can be restored by altering the high-frequency gain (Pallett and Scopes, 1965) or by means of an automatic baseline-restoring circuit. In practice this represents little disadvantage because the patients we monitor are usually immobile for one reason or another. We have occasionally encountered tracings which appeared inverted, and this has been found to result from wrong positioning of the electrodes or from poor skin contact. It is noticeable that in children the cardiac component of the tracing is much more prominent than in adults.

Our intensive therapy unit nurses have little difficulty in understanding the significance of the tracings. They recognize the E.C.G. immediately, and, after seeing the position of the electrodes, soon decide that the other tracing shows respiration. The cardiac component of the impedance tracing is less often recognized immediately, but is understood once it

has been explained. As the height of the respiratory waves is proportional to the tidal volume the system is meaningful, unlike a tracing of airway or oesophageal pressure. This enables the observer to form the same appreciation of the patient's respiration as can be obtained by close observation of the movement of the chest.

Calibration is carried out by measuring the height of the tracing at the same time as the breath is measured with a spirometer. For monitoring purposes we use either a Wright spirometer or a calibrated concertina bellows which can be used to give a breath of known volume to an apnoeic patient. These methods are accurate enough for clinical purposes, in spite of the relatively large standard deviations of the impedance changes reported by Kubicek *et al.* (1964). For adults we normally employ a sensitivity of 1 cm./100 ml. volume change, but in children we usually increase this to 2 or 3 cm./100 ml.

We have found, as we had originally hoped, that changes in tidal volume and upper airway resistance are immediately apparent. We regard the display of these changes as an essential property of any respiratory monitoring system. Fig. 2 shows the effect of clamping the endotracheal tube connexion in a spontaneously breathing anaesthetized patient. Fig. 3 shows the same procedure in a fully relaxed anaesthetized patient receiving artificial ventilation. In both these cases the small cardiac waves are seen to persist while the

FIG. 2.—Tracing taken from a spontaneously breathing anaesthetized patient. The larger variations are due to respiration and the smaller to the heart beat. The black line shows when the endotracheal connexion was clamped, causing a complete obstruction to respiration. The respiratory wave disappeared in spite of the patient's efforts to breathe, but the cardiac wave remained. (Paper speed 5 mm./sec.) FIG. 3.—Tracing taken from the same anaesthetized patient during artificial ventilation after receiving a relaxant. Only the cardiac waves could be seen when the airway was clamped for 12 seconds (black line). (Paper speed 5 mm./sec.) FIG. 4.—Recording from the same patient when the airway was partially clamped (black line) during artificial ventilation. The tidal volume fell to about half its previous value. (Paper speed 5 mm./sec.) FIG. 5.—Tracing showing the effect, again in the same artificially ventilated patient, of disconnecting the ventilator (black line). As in Fig. 3, only the cardiac waves can be seen. (Paper speed 5 mm./sec.)

respiratory waves are absent. In Fig. 4, recorded from the same relaxed patient, the airway is only partially obstructed, resulting in an obvious reduction of tidal volume. Fig. 5 shows the effect, again in the same apnoeic patient, of disconnecting the ventilator. This pattern is indistinguishable from that shown in Fig. 4, demonstrating that this technique reveals the essential point—namely, that ventilation of the lungs has ceased. So far as we know this is the only method of monitoring which cannot give a wrong indication in these circumstances.

It is also possible to study the shape of the respiratory wave-form with the impedance spirometer. The tracing follows closely all changes in the volume of air in the lungs, so that it is possible to measure not only the tidal volume but the rate of change of volume, both in inspiration and in expiration. Fig. 6 was recorded on a patient ventilated with a Barnet Mark III ventilator. This machine, though theoretically a constant pressure generator, in practice operates as a

FIG. 6.—Tracing showing the respiratory wave-form when using a Barnet Mark III ventilator. This machine functions as a constant flow generator and the upstroke of the respiratory wave shows the expected straight line. The downstroke, as the patient expires to atmosphere, is exponential. (Paper speed 5 mm./sec.) FIG. 7.—Tracing showing the wave-form when using an East-Radcliffe ventilator to produce the same tidal volume as in Fig. 6. In this case both the upstroke and the downstroke are exponential. This wave-form is typical of a constant pressure generator. (Paper speed 5 mm./sec.)

constant flow generator (Mapleson, personal communication) and the tracing shows the expected straight line during the inspiratory phase. Fig. 7 was recorded when the same patient was being ventilated with an East-Radcliffe ventilator at approximately the same rate and tidal volume. In this case the tracing shows the exponential curve expected of a constant pressure generator. In both these tracings the expiratory portion is identical, being an exponential decay as the patient expires to atmosphere. The technique may therefore prove helpful in the treatment of asthmatics in whom this decay is prolonged because of the increased lower airways resistance.

Summary

A technique for monitoring respiration is described which is simple to use and simple to understand. Three electrodes are attached to the patient's chest and changes in trans-thoracic electrical impedance are displayed on an oscilloscope. This tracing reflects the volume of air in the lungs so that the tidal volume, respiratory rate, and respiratory wave-form can be immediately appreciated by those attending the patient.

Additional advantages are that an E.C.G. can be obtained from the same electrodes and that the impedance tracing shows small variations in time with the heart beat. It therefore gives a valuable indication of the function of the heart as well as of respiration. The display provides direct, reasonably accurate, and conceptually simple indications of these two vital factors, important points where nurses are concerned. We feel that this technique is worthy of further trial.

Haemoglobin E and α -Thalassaemia*

P. WASI,[†] M.B., PH.D.; M. SOOKANEK,[†] M.B.; S. POOTRAKUL,[†] M.B., M.S.; S. NA-NAKORN,[†] M.D.
 A. SUINGDUMRONG,[†] M.B.

Brit. med. J., 1967, 4, 29-32

Haemoglobin Bart's was first described by Ager and Lehmann (1958). The fast-moving haemoglobin earlier reported by Fessas and Papaspyrou (1957) is believed to be identical with Bart's (Fessas, 1959). This haemoglobin has been found by Hunt and Lehmann (1959) to consist entirely of γ -polypeptide chain, thus having the molecular formula of γ_4 ; Hbs A, F, and A_2 are $\alpha_2\beta_2$, $\alpha_2\gamma_2$, and $\alpha_2\delta_2$ respectively.

Hb Bart's, in extremely variable amount, has been found in conditions ranging from the asymptomatic newborns (Tuchinda *et al.*, 1959; Lie-Injo, 1959; Vella, 1959; Hendrickse *et al.*, 1960; Fessas, 1960; Lie-Injo and Ti, 1961; Schneider and Haggard, 1961; Minnich *et al.*, 1962; Silvestroni and Bianco, 1962; Weatherall, 1963) to the lethal Hb Bart's hydrops foetalis

syndrome (Lie-Injo *et al.*, 1962; Banwell and Strickland, 1965; Diamond *et al.*, 1965; Wong, 1965; Pootrakul *et al.*, 1967). Apart from its presence in minute amount in the cord blood of apparently every newborn, the occurrence of Hb Bart's is believed to be a result of α -thalassaemia gene. The latter depresses α -chain synthesis, resulting in excessive γ -chains, which then polymerize to the tetrameric form- γ_4 .

In Thailand Hb E, β -, and α -thalassaemias are prevalent (Na-Nakorn *et al.*, 1956; Flatz *et al.*, 1965; Wasi *et al.*, 1967). These genes, in different combinations, give rise to various conditions and diseases, such as β -thalassaemia homozygosity (Hbs A+F), β -thalassaemia-Hb E disease (Hbs E+F), and Hb H disease (Hbs A+H). Beginning from 1961, we have frequently encountered another disease characterized by the presence of three haemoglobins, A, E, and Bart's. Genetical data indicate that individuals with this disease inherit three abnormal genes—namely, a classical or α -thalassaemia, a milder

or α -thalassaemia₂, and Hb E genes. We wish here to present the clinical and haematological data of this α -thalassaemia₁/ α -thalassaemia₂-Hb E disease in 21 patients.

Materials and Methods

Standard haematological techniques were employed. The counting of red blood cells in the latter patients was done in Coulter's electronic counter; quantitative osmotic fragility of the red cells was also switched from the standard method (Dacie, 1960) to Danon's (1963) automatic fragiligraph. Red cell inclusion bodies were demonstrated according to the technique previously described (Na-Nakorn, *et al.*, 1965). The acid elution method of Betke and Kleihauer (1958) was used to demonstrate individual cells containing Hb F.

Haemolysate was prepared according to Singer *et al.* (1951). Originally haemoglobin types were determined by paper and cellulose acetate electrophoreses, and the relative amount of each fraction was obtained by starch block electrophoresis (Kunkel and Wallenius, 1955; Gerald and Diamond, 1958). Later all the haemoglobin typings were done in starch-gel tris-borate-E.D.T.A. buffer, pH 8.6 (Smithies, 1959). Haemoglobin fractions were quantitated by electrophoresing on cellulose acetate in tris-borate-E.D.T.A. buffer pH 8.6 for one hour, each haemoglobin type being eluted with water from the cut strip, the optical density being read in Beckman B spectrophotometer. Alkali-resistant haemoglobin was measured with the one-minute method (Singer *et al.*, 1951).

Results

General and Clinical Description.—Table I summarizes the general and clinical data. The patients were 5 to 38 years old,

those younger than 13 having been seen in the department of medicine only through family investigation. Ten were males. All had Thai ethnic background with mixed Chinese and Mon, each in one instance. They were from central or north-eastern Thailand. Retardation of development was observed in eight cases, being most pronounced in Case 21. "Thalassaemic mongoloid" facies (Fig. 1) was definite in two and suggestive in 12. All were anaemic, and 17 were mildly to moderately jaundiced when first seen. The liver was not palpable in four cases, being 5 to 8 cm. below the right costal margin in the rest. Splenomegaly was noted in all except Case 14, and varied from being just palpable to 18 cm. below the left costal margin.

Haematological Findings.

—These are summarized in Table II. The means of the haemoglobin concentration, red blood cell count, and haematocrit in the 21 patients were 6.9 (S.D. 1.6) g./100 ml., 4.29 (S.D. 1.14) million/cu. mm., and 27 (S.D. 6) % respectively. Both red cell indices and morphology showed hypochromicity and microcytosis; anisocytosis, poikilocytosis, nucleated red cells, polychromasia, and leptocytosis were always observed (Fig. 2). Reticulocyte counts were 3–17%. Quantitative red cell osmotic fragility, either with the

— = not estimated.

standard technique or with Danon's automatic fragiligraph, was constantly decreased. On mixing the blood with methylene blue solution inclusion bodies, unlike those in Hb H disease, were always seen but only in very few red cells (Fig. 3). Acid elution and counterstaining according to Betke's technique showed a few cells retaining haemoglobin (Fig. 4). ^{51}Cr red cell half-lives† in Cases 7, 9, 13, 16, and 21 were 3.5, 10, 8.5, 12, and 4 days respectively. The bone marrow examination in four cases showed marked erythroid hyperplasia and haemosiderosis.

Haemoglobin Types.—The major haemoglobin types in starch gel (Fig. 5) were A+E+Bart's. The level of Hb E fell in a

FIG. 2.—Case 16. Peripheral blood smear. (Wright's stained. $\times 1,280$.)

FIG. 3.—Case 18. Methylene blue fresh preparation ($\times 3,200$) showing characteristic presence of a few cells with inclusion bodies.

FIG. 4.—Case 21. Acid elution staining ($\times 1,280$) showing a few acid-resistant red cells.

rather narrow range between 13 and 15%, in most cases, the extreme values being 12.2 and 18.9%. Hb Bart's constituted 3.4 to 18.0, averaging 8.4%. Alkali-resistant haemoglobin, as determined by Singer's one-minute method, was slightly raised (Table II). A band of presumably Hb F was seen behind that of Hb A in both starch-gel and cellulose acetate electrophoreses; with the latter technique the amounts in Cases 10, 12, 13, 19, and 21 were 4.4, 3.9, 4.0, 3.9, and 7.0% respectively. With both starch-gel and cellulose acetate electrophoreses a faint band of haemoglobin was seen cathodal to Hb E at pH 8.6 (Fig. 5). The amount of this slow-moving haemoglobin was 0.53–1.30%. Occasionally a faint band of haemoglobin at Hb H position was observed.

Other Findings.

X-ray examination of the skulls and long bones in 17 cases showed widening of the medulla typical of thalassaemic diseases in one case, and in two cases the pictures were suggestive. Serum iron was raised in most cases. Conjugated bilirubin level was normal, but the total value was

raised up to 5.5 mg./100 ml. Serum globulin was above 4 g./100 ml. in three out of nine patients, and serum electrophoresis showed gammaglobulin of 25% or over in five out of eight cases. Serum flocculation tests were often positive. The fasting blood sugar, serum alkaline phosphatase, transaminases, cholesterol, and sulphobromophthalein excretion, determined in five cases, were within normal limits.

Clinical Course.—The patients remained anaemic all the time, though the haemoglobin level may fluctuate considerably. Folic

FIG. 5.—Horizontal starch-gel electrophoresis in tris-borate-E.D.T.A. buffer, pH 8.6, stained with ortho-dianisidine.

FIG. 6.—Family of Case 2. Detailed genetical data will be described elsewhere.

acid orally did not seem to alleviate the anaemia. Hypersplenism was noted in Case 21. Splenectomy had been performed in Cases 2, 3, 4, 10, 14, and 21, with a slight improvement of anaemia in Cases 14 and 21.

Genetical Findings.—Family members of the patients were examined, but the results are not presented here. Only representative findings from the family of Case 2 are condensed into Fig. 6.

† Done by Dr. V. Viranuvatti and others, of the Faculty of Medical Technology.

• Discussion

That this Hb A + E + Bart's disease is connected with thalassaemia is evident from thalassaemic stigmata in the patients themselves and in their parents, siblings, and offspring. This type of thalassaemia is the low Hb A₂ or α -chain variety of thalassaemia. Two forms of α -thalassaemia have been identified in the Thai population (Wasi *et al.*, 1964): α -thalassaemia₁ (α -thal₁) is the classical or the most severe form, and α -thalassaemia₂ (α -thal₂) is the mildest type which cannot be identified in heterozygotes. Those homozygous for the α -thalassaemia₁ gene die during intrauterine existence with the clinical findings of the Hb Bart's hydrops foetalis syndrome (Pootrakul *et al.*, 1967). The α -thal₁/ α -thal₂ combination results in Hb H disease. Genetic analysis of the families reported here will be presented in detail elsewhere. They indicate that the patients with Hb A + E + Bart's disease are carrying the Hb E gene and those for α -thal₁ and α -thal₂. This condition has been reported as well by Tuchinda *et al.* (1964), who discussed the interaction of two different α -thalassaemia genes and Hb E as one of the possible aetiologies.

Clinically this disease cannot be differentiated from β -thalassaemia homozygosity, β -thalassaemia-Hb E, and Hb H diseases, much prevalent in Thailand. The severity of the already recognized disease forms appears to be in the following order: α -thalassaemia₁ homozygosity (Hb Bart's hydrops foetalis), β -thalassaemia homozygosity, β -thalassaemia-Hb E, α -thal₁/ α -thal₂-Hb E, and α -thal₁/ α -thal₂.

Haemoglobin phenotype of A + E + Bart's is the hallmark of the disease under present discussion. In contrast to Hb H disease, in which inclusion bodies are demonstrable in the majority or all of the red cells, in α -thal₁/ α -thal₂-Hb E disease only a few red cells show inclusion bodies. The non-overlapping numbers of red cells containing inclusion bodies in these two conditions have led us to correct diagnosis previous to electrophoresis in all instances. These scanty inclusion bodies in the red cells of the patients with Hb A + E + Bart's probably represent Hb H, which is present at too low concentrations to be readily detected by electrophoresis. Hb E, which in heterozygotes is present in about 30% of total haemoglobin, represents about 14% of the total haemoglobin in this disease. Three reasons for the reduced quantity of Hb E in this circumstance may be considered. Firstly, the α -thal₁/ α -thal₂ combination, in addition to suppressing α -chain synthesis, has an inhibitory effect upon Hb E production (Tuchinda *et al.*, 1964). Secondly, unequal distribution of haemoglobin types among red cells may be associated with differential survival as found in Hb H disease (Gabuzda *et al.*, 1965). Finally, β_2 subunits may compete for α_2 subunits more successfully than β_2 E subunits. In view of insufficient data it is not appropriate to discuss these possibilities at length here.

In this disease both Hbs F and Bart's are raised irrespective of the patient's age. The increased amount of alkali-resistant haemoglobin is due to both types of haemoglobin, since Hb Bart's is partially alkali-resistant. According to Betke's technique, cells containing Hb F are relatively resistant to acid elution. In Hb A + E + Bart's disease a few cells are obviously resistant. Whether they represent cells containing only Hb F or Hb Bart's as well is not yet known.

The apparent decrease in β -chain synthesis in α -thalassaemia has been previously discussed (Rucknagel, 1964; Pootrakul *et al.*, 1967). As judged by the amount of Hbs F and Bart's found in α -thal₁/ α -thal₂-Hb E disease the quantity of γ -chain produced in this condition is obviously greater than that in Hb H disease. This suggests that the amount of β -chain synthesis in the former is less than in the latter, since the quantity of γ and β chains is reciprocally related. This would indicate that, for reasons not yet clear, when the Hb E gene is present in addition to the α -thal₁ and α -thal₂ genes a reduction in β -chain synthesis occurs. Thus very little Hb H is found in this disease, despite the α -thal₁/ α -thal₂ genotype which is identical to that in Hb H disease.

The haemoglobin band slower than Hb E has not yet been identified. Its absence in both parents suggests that it is not a result of primary mutant gene action. It is most likely δ_1 , as found in Hb H disease (Dance *et al.*, 1963) and/or β_2 E. Further investigation is in progress.

The patients with this disease seem to benefit only from blood transfusion, and from splenectomy when hypersplenism is present. Liver damage often handicaps the victims. The patients with these various combinations of thalassaemias and Hb E, about 100,000 in number as estimated from gene frequencies, present a socio-economic problem to Thailand.

Summary

The clinical and haematological study of 21 patients in Thailand with a new disease is described. It is similar to a thalassaemia major disease clinically. Hepatosplenomegaly was almost consistently detected, the mean haemoglobin concentration was 6.9 g./100 ml., the red cells showed strong stigmata of thalassaemia, and the erythrocytic life-span was shortened. This disease is characterized by the presence of inclusion bodies in very few red cells, and haemoglobin phenotype of A + E + Bart's with about 14% Hb E and 8% Hb Bart's. Elevation of Hb F was demonstrated electrophoretically, morphologically, and by the alkali denaturation test. Small amounts of an unidentified haemoglobin slower than E, probably δ_1 and/or β_2 E, were also detected. Genetical data suggest that this disease is a result of a combination of three abnormal genes—namely, the more usual type of α -thalassaemia or α -thalassaemia₁ gene, a milder or α -thalassaemia₂ gene, and Hb E. Anaemia in these patients was, although fluctuating in degree, perpetual. Splenectomy had been done in six patients, with a slight improvement of anaemia in two—one with hypersplenism.

Medical Memoranda

Cantharides Intoxication

Brit. med. J., 1967, 4, 33

Preparations containing cantharides, commonly known as "Spanish fly," have been used since the time of Hippocrates for conditions such as dropsy and amenorrhoea, and for the aphrodisiac properties that it is wrongly thought to possess. Cantharides is the active component contained in the ovaries, soft tissues, and blood of the blister beetle *Cantharis vesicatoria*. It contains not less than 0.6% of cantharidin (3:6-epoxy-1:2-dimethylcyclohexane-1:2-dicarboxylic anhydride), which is the active principle. The fatal dose of cantharidin is described as being less than 60 mg. (Nickolls and Teare, 1954).

Only four cases (*Pharm. J.*, 1963; Nickolls and Teare, 1954; Craven and Polak, 1954; Lécuyer, 1954), all terminating in death, have been reported in the English medical literature in the past 25 years. In the world literature 30 cases have been described since 1900.

CASE HISTORY

A man aged 42 was admitted to hospital at 2.15 a.m. on 9 August 1966. He had previously been in good health, except for two episodes of "nephritis" when aged 10 and 22 years.

At 5.30 p.m. he had taken a teaspoonful of liquor epispaeticus, which he knew contained cantharidin (approximately 20 mg.) to increase his libido, even though he had read of the man who caused the death of two typists by concealing cantharides in coconut ice (Nickolls and Teare, 1954; Craven and Polak, 1954).

One hour after taking the mixture symptoms started with the onset of frequency of micturition and severe dysuria. Approximately two hours later he felt nauseated and vomited. He micturated five times between 9 and 10 p.m., each specimen becoming progressively more blood-stained. Half an hour later he was passing pure blood, and had abdominal discomfort accompanied by bouts of diarrhoea. He continued to have haematuria and developed priapism; a few hours later he became worried and decided to seek medical advice.

On examination he was pale and extremely anxious. There was no pyrexia and his blood pressure was 120/80. The mucous membranes and throat were reddened, but blistering was not evident. Generalized tenderness was present over the abdomen and the bladder was palpable. The penis was erect and blood was present at the tip of the urethra. The central nervous, respiratory, and cardiovascular systems were normal.

The urine was loaded with protein (300 mg./100 ml.) and blood was visible macroscopically; pus, red blood, and scanty epithelial cells were seen on microscopy. No casts were present.

Laboratory Investigations.—Serum urea was 41 mg./100 ml., serum sodium 133 mEq/l., potassium 4.4 mEq/l., and bicarbonate 22 mEq/l. Total protein 6.7 g./100 ml. His haemoglobin was 13.8 g./100 ml., and the white blood cell count was 16,300/cu. mm. E.C.G., chest, and straight abdominal x-ray films were normal.

It was thought that a stomach wash-out performed nine hours after ingestion would be of no value. He was therefore treated with a high fluid intake of milk, a magnesium sulphate enema, analgesics, and sedation.

The next day ulceration and blistering of the mucous membranes of both cheeks, the tongue, and palate were observed. These responded well to hydrocortisone pellets. His blood pressure was maintained, and the daily urinary output remained at approximately 2 litres per 24 hours. The priapism subsided spontaneously and within four days the urinary abnormalities had resolved.

When seen as an outpatient one month later he was extremely fit. His haemoglobin was 13.4 g./100 ml. and serum urea 35 mg./100 ml., and his urine showed no abnormality.

DISCUSSION

Liquor epispaeticus contains: cantharidin 400 mg., castor oil 2.5 ml., colophony 1.2 g., plus acetone to 100 ml.

Acute renal damage after cantharides poisoning was documented as long ago as 1913 (Pearce). Dérobert and Le Breton (1957) described the case of a 77-year-old man who died from cantharidin poisoning, and at necropsy the most significant findings were those of acute tubular necrosis. Nickolls and Teare (1954) showed that microscopically there was haemorrhage into the tubules, producing tubular epithelial damage. Lécuyer (1954) stated that the acute tubular necrosis is due to the direct toxic action of the drug. It is possible, however, that the toxic action is aggravated by shock, which results in diminished renal blood flow. Powell (1907) reported chronic renal disease with associated contracted kidneys after cantharides ingestion.

No specific treatment is available. Csiky (1958) described four cases of pure cantharides poisoning; all the patients lived. His treatment was similar to ours, but he stated that oil, milk, and alcohol should not be taken as they aid absorption of the drug.

Management of the renal disorder and the associated fluid and electrolyte imbalance is probably the most important aspect of cantharides ingestion. As diminished renal blood flow and a reduced glomerular filtration rate are well described, acute tubular necrosis must be anticipated. Treatment will depend on urinary output, specific gravity, and the signs and symptoms of dehydration.

In none of the reported cases was there any evidence of an increase in libido. The myth that cantharides is an aphrodisiac should be destroyed, as its use for this purpose is fraught with danger and it is this property alone that perpetuates its illegal sale.

My thanks are due to Professor M. D. Milne for permission to publish this case, and to Drs. J. D. Swales and D. G. Gibson for their helpful advice.

Dangerous Consequence from Use of Phenytoin in Atrial Flutter

Brit. med. J., 1967, 4, 34

Phenytoin sodium (Epanutin)* has been used successfully in various ventricular and supraventricular arrhythmias (Leonard, 1958; Dreifus *et al.*, 1964; Conn, 1965) and has been recommended for the treatment of digitalis-induced tachycardias (Conn, 1965; Lang *et al.*, 1965; Ruthen, 1965; Smith, 1966). It would therefore appear to be a suitable drug for patients who require immediate termination of a rapid arrhythmia in the face of an unclear history of digitalis, diuretic, and potassium intake. For this reason we wish to record a dangerous complication of this drug—namely, the conversion of paroxysmal atrial flutter with 2:1 block to 1:1 conduction with a ventricular rate of 300 per minute. The decision to use phenytoin was made because this patient was in acute pulmonary oedema and required urgent treatment; she had been treated for many years with digitoxin and a thiazide diuretic without potassium supplements, and digitalis intoxication could not be excluded.

CASE REPORT

A 38-year-old Negro woman with chronic rheumatic heart disease was admitted to Cook County Hospital in acute pulmonary oedema.

Electrocardiographic tracing showing paroxysmal atrial flutter with 2:1 conduction (A). The administration of phenytoin led to the establishment of 1:1 conduction with a ventricular rate of 300 a minute (B). The patient later reverted to sinus rhythm after administration of digitalis (C).

She had had a mitral commissurotomy nine years before admission; in recent years symptoms recurred and she had become progressively incapacitated by exertional dyspnoea. One day before admission she developed palpitations, haemoptysis, and severe breathlessness at rest. She had been treated with digitoxin 0.1 mg. a day, thiazide diuretics, but no potassium supplements up to the day of her admission.

Physical examination revealed a woman in acute distress. The pulse rate was 150 a minute and was not affected by carotid sinus pressure. Blood pressure was 110/80 mm. Hg. The heart was not enlarged, but she had the physical signs of mitral valve disease and pulmonary oedema. An electrocardiogram showed atrial flutter at a

rate of 300 and a ventricular rate of 150, with a 2:1 atrioventricular block (see Fig.).

With electrocardiographic monitoring a slow intravenous injection of phenytoin sodium was begun. After two minutes, when approximately 150 mg. had been injected, the heart rate increased to 300 and 1:1 conduction was observed. Deslanoside (Cedilanid) 0.4 mg. was given intravenously and after five minutes she reverted back to her previous rhythm. An additional 0.4 mg. of deslanoside was subsequently given and she converted to sinus rhythm at a rate of 78. The serum potassium level at the time of admission was later reported to be 3.8 mEq/l.

Clinical evaluation at a slow heart rate revealed signs of tight mitral stenosis. The results of cardiac catheterization in February 1965 were later obtained; the mitral valve area was 0.6 sq. cm. Operation was refused at that time.

COMMENT

Phenytoin, while effective in stopping aconitine-induced atrial flutter in experimental animals, has been found to be generally ineffective in treatment of this arrhythmia in man (Conn, 1965; Ruthen, 1965). Nevertheless, Friedberg (1966) has referred to one patient in whom the drug may have been effective in converting atrial flutter to sinus rhythm. Our patient was in acute distress due to pulmonary oedema, and the possibility of digitalis intoxication, though rarely presenting as atrial flutter, was seriously considered; hence the decision to give intravenous phenytoin. The patient responded by the establishment of 1:1 conduction with an extremely rapid heart rate.

The mechanism of action of phenytoin in cardiac arrhythmias is not clear. Evidence has been presented that it decreases intracellular sodium content in cardiac muscle (Dreifus *et al.*, 1964; Ruthen, 1965). Clinically, the action of phenytoin is similar to that of quinidine and antazoline—that is, depression of excitability, conductivity, and contractility of cardiac muscle (Friedberg, 1966). Production of 1:1 conduction has been reported with both quinidine and antazoline (Dreifus *et al.*, 1964) and perhaps might also be expected to occur with phenytoin. We believe that the above case shows that intravenous phenytoin should not be used in atrial flutter with block, unless there is overwhelming evidence of digitalis intoxication.

Cardiac Involvement in Psittacosis

Brit. med. J., 1967, 4, 35-36

Involvement of the heart during the course of psittacosis is extremely rare if one is to judge from the few reports in the literature. This prompted us to record the following case.

CASE REPORT

An 18-year-old youth was admitted to hospital on 16 July 1965. Five years previously he had been in hospital because of typhoid. He said that he often caught and handled wild birds only to release them soon after. The last occasion on which he had done this was two weeks before taking ill.

His illness began two weeks before admission with the appearance of severe headache and fever, the latter persisting till admission and varying between 37 and 38° C. Soon after taking ill he experienced pain in his throat and a burning sensation in the retrosternal area, which caused great difficulty in swallowing. In addition, he developed such severe pain in the muscles of both legs that he was unable to stand unassisted.

On examination he appeared to be mildly ill and pale. Oral temperature was 38.8° C., blood pressure 110/80, and radial pulse 90 a minute and regular. The heart was normal in size. Neither cardiac murmurs nor a pericardial friction rub were heard. All peripheral pulses were palpable and equal.

Numerous white shallow ulcers were visible on the soft palate and on the fauces. A few ulcers were seen on the oropharynx. There was no lymphadenopathy. Lungs were clear to percussion and auscultation. The liver and spleen were not palpable. His calf muscles were exquisitely tender on palpation and the slightest movement evoked severe pain. There were no signs of thrombophlebitis. Neurological examination was unrevealing.

The erythrocyte sedimentation rate was 11 mm. an hour (Wintrobe), haemoglobin 12.0 g./100 ml.; leucocyte and platelet counts were normal. Blood urea, electrolytes, bilirubin, alkaline phosphatase, and aspartate aminotransferase were normal. Blood lactic dehydrogenase was 220 units (normal range 83-185), hydroxybutyric

Electrocardiogram taken soon after admission. Negative T waves are seen in leads I, II, aVL, V₅, and V₆.

dehydrogenase 198 units (normal range 55-150), and aldolase 4.2 units (normal range 2.3-6.4). Thymol turbidity, thymol flocculation, and Lugol's test were normal. Serum iron was 30 µg./100 ml. Plasma protein was 8.5 g./100 ml. (albumin 3.5 g., globulin 5 g.); electrophoresis on starch gel showed slight hypergamma-globulinaemia. The Wassermann reaction was positive, but reverted to normal five weeks later. Psittacosis complement-fixation test was positive in a titre of 1:320 on 7 July, 1:480 on 25 July, 1:240 on 23 August, and 1:160 on 9 September. Urinalysis was normal. The 24-hour urinary creatine excretion was 154 mg.

Chest x-ray examination on admission showed a normal heart and lungs. Fluoroscopy of the heart five days later was normal.

Electrocardiograms, repeated several times during his stay in hospital, showed sinus rhythm at a regular rate of 80 a minute. Negative T waves were seen in leads I, II, aVL, aVF, V₅, and V₆; the Q-T interval was prolonged to 0.42 second (see Fig.). An E.C.G. performed during his previous admission was normal.

The patient's symptoms and signs subsided gradually during a two-weeks stay in hospital. Results of the serological tests were received after complete clinical recovery. Three weeks after discharge he was completely symptom-free, and an E.C.G. showed similar findings to those during his stay in hospital.

COMMENT

The diagnosis of psittacosis in this case is based on the serological findings, for a titre of 1:16 is regarded as positive (Rivers, 1952). The threefold rise in titre level to a peak of 1:480 is adequate evidence of active infection. The known limitations in interpreting the positive serology can be excluded rather readily. Both cat-scratch fever and lymphogranuloma venereum can produce false-positive reactions (Rivers, 1952; Kryslar and Altman, 1961), but the clinical picture in our case confidently excludes these diseases. False-positive serological reactions for syphilis have been described during the course of psittacosis (Allison and Dick, 1954; Grist and McLean, 1964).

The finding of cardiac involvement is the most interesting aspect of this case. This was clearly shown by the electrocardiographic changes in the T waves and prolongation of the Q-T interval. Such changes are indicative of myocarditis. The complaint of retrosternal burning made by our patient suggests that pericarditis may have been present as well, but an unequivocal diagnosis of pericarditis cannot be made in the absence of a friction rub or evidence of effusion.

Clinical accounts of cardiac involvement in psittacosis are few in the literature. The case has been reported of a patient with serologically proved psittacosis who manifested signs of pneumonitis, encephalitis, and myocarditis (Vosti and Roffwarg, 1961). The outcome was fatal. Electrocardiogram showed T-wave inversion in leads I, II, aVL, and V₁₋₆ and prolongation of the Q-T interval. Fatal myocarditis in a child was reported, in which serological proof of psittacosis was sought (Jannach, 1958). The diagnosis was established after examining tissue preparations obtained from two pet parrots that died three weeks after the child's illness. Characteristic Levinthal-Cole-Lillie inclusion bodies were seen in tissues of mice infected with suspensions of the parrots' tissues, and in the myocardium of the dead child. A case of psittacosis in which myocarditis could be inferred from the clinical picture has been reported, but electrocardiographic evidence was not presented (Valero, 1953).

In addition to the few clinical descriptions of myocarditis some cases have been described in which only pathological evidence of psittacosis myocarditis was presented (Lyon, 1956). In three other cases the mild T-wave changes are not convincing evidence of myocarditis, and the associated manifestations may well have been due to pneumonic involvement. Psittacosis pericarditis is similarly rare and only one case was encountered in the literature of recent years (Schoenemann and Gläsel, 1965).

When admitted to hospital our patient was bothered by two additional symptoms—namely, difficulty in swallowing and inability to stand because of exquisite muscle pain. The dysphagia can be explained by the mucosal lesions in the mouth, and if pericarditis was indeed present it may have contributed as well. The occurrence of oral ulcers has been described in psittacosis (Rivers, 1952). The pronounced calf tenderness was compatible, clinically, with a diagnosis of myositis. However, neither muscle biopsy nor electromyography was performed. The possibility of thrombophlebitis (Rivers, 1952)

seems unlikely in view of the patient's age, the symmetrical involvement, and the severity of the subjective manifestations in contrast with the paucity of the objective findings.

Urticaria after Insertion of Smith-Petersen Vitallium Nail

Brit. med. J., 1967, 4, 36

The cause of chronic urticaria is usually elusive. The following case report suggests that the nickel contained in a cast cobalt-chromium alloy (Vitallium) was responsible for symptoms of immediate type allergy.

CASE REPORT

On 11 January 1965 a woman of 65 sustained a fracture of the right femoral neck. The next day a Smith-Petersen Vitallium nail was inserted under halothane anaesthesia. On the day after operation pruritus and generalized urticaria developed, and these symptoms persisted for the next 10 months. During this time there was radiological healing of her fracture, but there was little weight-bearing on the limb on account of anginal congestive cardiac failure and three episodes of cerebral thrombosis. A right-sided hemiplegia followed one of these strokes.

On 8 December she was admitted to the Norfolk and Norwich Hospital for investigation of urticaria. Her major physical findings were right-sided flaccid hemiplegia, generalized urticaria, and dermatographism. Laboratory findings were as follows: haemoglobin 13.4 g./100 ml.; W.B.C. 5,600/cu. mm. (neutrophils 70%, lymphocytes 22%, monocytes 5%, eosinophils 3%); E.S.R. 11 mm. in one hour (Westergren); direct Coombs test negative; blood urea 25 mg./100 ml.; total serum proteins 6.62 g./100 ml. (albumin 4.6 g., globulin 2.02 g.). X-ray picture of chest and urinalysis were normal.

Discontinuation of current treatment (barbiturates, digitalis, and diuretics) produced no lessening of urticaria, and challenge with the drugs she had received before operation—Omnopon and scopolamine—led to no exacerbation. Routine patch testing showed an eczematous response to a solution of 2% nickel sulphate at 48 hours. A similar response was produced by a Vitallium nail strapped to the thigh for 48 hours. During patch testing there was no increase in severity of urticaria, but severe non-eczematous peri-orbital oedema developed at 48 hours and resolved within the following 12 hours. A scratch test with 2% nickel sulphate solution resulted in an itching weal (3 cm.) at 10 minutes, and was associated with patchy erythema and swelling of the same forearm for one hour. A passive transfer (Prausnitz-Küstner) test performed on a volunteer was positive. Patch and scratch tests with the other constituents of a Vitallium nail were negative.

Since the patient was bedfast and her fracture had healed clinically, the nail was removed on 10 January 1966 under local anaesthesia. Within 24 hours spontaneous urticaria resolved but dermatographism persisted. Exquisite and troublesome dermatographism was still present one year after removal of the nail.

COMMENT

At first this patient's urticaria was thought to represent an allergic reaction to drugs given postoperatively. It was she

who, for the wrong reason, suggested the correct line of investigation. She reported that during early married life she was said to be "metal sensitive," and that reports about her had appeared in the *British Medical Journal* and the daily press. A search through the *British Medical Journal* of the 1930s showed that she was referred to in a "Queries and Answer" series under the heading of "The Sympathetic Ring" (Jones, 1936). Her practitioner questioned the mechanism involved when the patient's gold ring became the colour of platinum when on her finger but reverted to a golden colour when placed on the mantelshelf overnight. Subsequent editorial comment (*Brit. med. J.*, 1936) summarized correspondence which suggested contact with mercury contained in soaps, ointments, and lotions. The patient had noted no skin change under her ring or other metal object.

Classically, the separate nature of immediate and delayed type allergy has been stressed. However, clinical experience and various reports in the literature suggest that these two types of allergy may exist in the same individual. Calnan (1956) noted the presence of urticaria in his series of nickel-sensitive patients, and Stoddart (1960) reported the case of a patient with delayed contact sensitivity to nickel who developed anaphylaxis after transfusion through a nickel-plated cannula. Shelley and Resnik (1965) studied seven patients with poison ivy dermatitis, and, in addition to showing skin sensitivity to poison ivy oleoresin ether extract, the patients showed the morphological change of basophil degranulation when challenged with poison ivy extract orally. Basophil degranulation in vivo and in vitro occurs during immediate type hypersensitivity (Shelley and Caro, 1962).

We are unable to date the onset of this patient's cutaneous sensitivity to nickel. She had noted no eruption under metal clips, buckles, suspenders, etc. We have concluded that delayed and immediate type antibodies existed, and that the latter reacted with nickel absorbed from the Vitallium nail. Her immediate freedom from urticaria after removal of the nail was dramatic, but the continuation of dermatographism has been a disappointment.

We are indebted to Mr. A. W. Laxen, of the London Splint Company Ltd., for the composition of the alloy whose trade name is Vitallium (chromium 27-30%, molybdenum 5-7%, iron 0.75%, carbon 0.5%, nickel 1%, silicon 1%, manganese 1%, cobalt balance).

Human Abortion Associated with Infection by Ovine Abortion Agent

Brit. med. J., 1967, 4, 37

Stamp *et al.* (1950) showed that abortion in sheep was caused by a virus-like agent, enzootic abortion of ewes or ovine abortion virus. In affected flocks, abortion, premature lambing, and the birth of decomposed lambs are striking clinical signs of the disease. These generally take place late in pregnancy, but a number of dead or weakly lambs may be born at the proper lambing time. The ewe is generally little affected in health, and the main clinical manifestations of the disease do not give a true incidence of infection. Healthy lambs may be born from apparently healthy ewes, yet the foetal membranes may show lesions and be infected. When these lambs, and surviving weakly lambs, mature and become pregnant they may abort. The infection remains latent until they develop placental tissue in which the virus multiplies selectively. This disease is endemic in sheep in South-east Scotland, and from here it has often spread to other parts. Several outbreaks occur in Ayrshire each year. The agent belongs to the Bedsonia group of organisms, common parasites of warm-blooded animals, some causing human infections such as ornithosis, trachoma, inclusion conjunctivitis, and lymphogranuloma venereum. The possible susceptibility of man to infection with other members of this group is obviously of interest. The following case is of human abortion attributable to the enzootic abortion of ewes virus.

CASE REPORT

A woman aged 22 was admitted to Ayrshire Central Hospital on 4 December 1965 complaining of headache, pain in the back, shivering and sweating, heartburn, and frequent vomiting. These symptoms had begun four days before admission. She had also been febrile during this time and had been given injections of penicillin and streptomycin without effect. She was just over six months pregnant.

On examination she was acutely ill, temperature 102.4° F. (39.1° C.). She was mentally rather confused and had some meningismus. No other abnormal clinical signs were present except for those expected in a febrile dehydrated patient. No obstetrical abnormality was found. Examination of peripheral blood showed anaemia and leucopenia, the haemoglobin being 8.8 g./100 ml., P.C.V. 27%, M.C.H.C. 32%, and W.B.C. 2,100/cu. mm., with white cells in normal proportions. Her blood urea level was 42 mg./100 ml.; serum sodium, potassium, and chloride levels were all low. Four blood cultures were sterile. Chest x-ray examination was negative. Bacteriological examination of sputum, urine, and faeces revealed no pathogens. Lumbar puncture showed clear fluid-cell count 1/cu. mm., protein 12 mg./100 ml. Liver-function tests were within normal limits, except for a slight increase in thymol turbidity. Widal, Paul-Bunnell, and *Brucella abortus* agglutination tests were negative. She had a swinging temperature for four days, during which time she was treated symptomatically, and then was given tetracycline 500 mg. six-hourly for eight days. Her symptoms soon abated; the temperature settled in 48 hours and thereafter remained normal, and she made a good recovery. Four days after tetracycline was stopped she aborted precipitately and with very little warning. The placenta appeared unhealthy, being covered with a dirty greyish exudate. Histological examination showed infarcted placental tissue. There was little upset from this event, and she was dismissed home a few days later.

Antibody Titres of Patient's Serum

Test	Date of Serum		
	6/12/65	17/12/65	12/1/66
Complement fixation: Bedsonia group	16	512	512
Microagglutination: B.A.E. (Q18 strain)	<20 (±)	20	640
Psittacosis	<20	<20	<20
Rickettsiae*	<20	<20	<20

* *R. prowazeki*, *R. mooseri*, *R. burnetii*; trace reaction with *R. conorii*.

Virological Investigations.—Serological tests gave no evidence of infection with influenza A, B, or C, adenovirus, or Q fever. As shown in the Table, diagnostic rising antibody titres were found by complement-fixation tests with Bedsonia-group antigen and by micro-agglutination tests with enzootic abortion of ewes virus but not with psittacosis or rickettsial antigens. Attempts to show enzootic abortion of ewes virus in placenta by microscopical examination of stained smears or attempted isolation in mice were unsuccessful, as only a small specimen was available, and this had decomposed through delay in transit to the laboratory.

Epidemiological Investigations.—There was no history of recent illness of the husband or other human contacts. No history of direct contact with animals or birds was obtained except for occasional visits to a house with a budgerigar and from a friend with a dog. The patient's home bordered on agricultural land on which sheep were kept.

COMMENT

Human infection with enzootic abortion of ewes virus has rarely been recognized. Because of its relatively low pathogenicity for man, enzootic abortion of ewes virus is often used in preference to the dangerous psittacosis agent for laboratory purposes—for example, preparation of group-specific complement-fixing antigen for routine diagnostic tests. Barwell (1955) described an accidental laboratory infection with enzootic abortion of ewes virus which took the form of extensive nonfatal pneumonia.

In the present case the rising titres of complement-fixing antibody leave no doubt that the illness was associated with infection with an agent of the Bedsonia group, and the micro-agglutination tests incriminate enzootic abortion of ewes virus as the member of the group concerned. Human infections with organisms of the Bedsonia group are not uncommon, though the frequent failure to identify avian sources of infection (Grist and McLean, 1964) suggests that some may be acquired from animals—for example, sheep which were in the vicinity of our patient's home.

Experimental infections with enzootic abortion of ewes virus can cause abortions in pregnant cattle, rabbits, and rats (Giroud and Dumas, 1959; Payne and Belyavin, 1960). The relative resistance of non-pregnant animals and the localization of lesions and infections in placenta suggest that the presence of placental tissue facilitates establishment of the infection. Selective multiplication in placental tissue has also been shown with other organisms of the Bedsonia group (Parker and Younger, 1963; Pierce *et al.*, 1963).

Lefebvre (1962) and Giroud (1966) have reported an association between human abortion and infection with various organisms of the rickettsia and Bedsonia groups. Our case provides evidence of this in Britain, and it seems possible that investigations of pregnant women with fever or abortion might show that this condition is more common than is generally recognized.

We thank members of the Maternity Unit, Ayrshire Central Hospital, Irvine, for their help in the management of this patient.

Treatment and Survival after Massive Overdose of Adrenaline

Brit. med. J., 1967, 4, 38

Infiltration of solutions of adrenaline is often used to produce a degree of haemostasis, and though dilutions vary considerably the normal maximum dose is restricted to about 0.5 to 1 mg., while reported maximum tolerated doses with survival are in the order of 7 to 8 mg. (Freedman, 1955). This paper reports the inadvertent subcutaneous injection of 16 ml. of the undiluted 1:1,000 solution (16 mg.). The patient survived with no residual disability, and consideration of the treatment used may be of benefit to anyone faced with a similar situation.

CASE REPORT

An otherwise healthy woman aged 23 was admitted to hospital for tympanoplasty under general anaesthesia. Six months previously she had had a left mastoidectomy and a right cortical mastoidectomy and on each occasion anaesthesia with thiopentone, suxamethonium, nitrous oxide, oxygen, and halothane was entirely uneventful. As it was planned to use a local injection of adrenaline, anaesthesia was induced with thiopentone, and endotracheal intubation under suxamethonium was followed by intermittent positive ventilation with nitrous oxide and oxygen, relaxation being maintained by tubocurarine.

After induction, an intravenous infusion of 5% dextrose was set up while the preliminary surgical procedures were taking place. After infiltration of adrenaline, which was thought to be 1:200,000 dilution, the patient's pulse rate became uncountable and her blood pressure rose to unrecordable figures. It was realized that a 1:1,000 dilution of adrenaline had been used and the patient had then received 16 mg. of adrenaline.

Trimetaphan camsylate (Arfonad) 500 mg. was immediately added to the infusion and run in rapidly while 5 mg. of phentolamine (Rogitine) was given into another vein. Within two minutes the pulse rate fell slightly, though it was still too fast to count, and the blood pressure fell to 190 mm. Hg systolic from its previous value of over 300 mm. Hg. Diastolic pressure was difficult to record, but the venous pressure was obviously grossly raised, as shown by the difficulty in maintaining any intravenous infusion during the next three hours. This difficulty persisted in spite of a large catheter inserted into the saphenous vein, and on occasions a pressure pump was required to maintain the infusion.

When about 250 mg. of trimetaphan had been given quickly, over 20 minutes, the pulse rate settled to approximately 150 a minute, the blood pressure falling to about 200 mm. Hg systolic and remaining at this level during the next one and a half hours. When a further 100 mg. had been given more slowly (over the next half-hour) the systolic blood pressure fell to 50 mm. Hg and the ganglion-blocking drug was discontinued. The pressure remained between 70 and 90 mm. Hg for the next 36 hours despite the intravenous administration of 200 mg. of hydrocortisone. Methylamphetamine (Methedrine) 2.5 mg., given during this period of hypotension when the systolic pressure was 80 mm. Hg, produced a transient rise to 140 mm. Hg. Two days after the incident the pressure began to rise spontaneously and reached 120/70 by the

fourth postoperative day. The pulse rate also took a long time to settle and was not under 100 until the fourth postoperative day.

It is interesting to note that when the error was first realized the appearance of the patient was normal, but within five minutes this had changed to a state reminiscent of acute peripheral circulatory failure with cold white skin. This latter persisted for several days and was the most striking feature of this case.

The patient was discharged home on the eighth day with no residual disability, and subsequent progress has been entirely satisfactory.

COMMENT

The choice of anaesthetic in this case was fortunate, because had nitrous oxide, oxygen, and halothane been used (as on the previous occasions) it is very likely that the patient would have developed ventricular extrasystoles or even ventricular fibrillation (Millar, Gilbert, and Brindle, 1958; Rosen and Roe, 1963). The use of controlled ventilation was also favourable in that it maintained a low PCO_2 and prevented a rise in endogenous catecholamine secretion.

After realizing the error in the dose of adrenaline it was decided to continue with the proposed operation, because it was felt that the minor surgical procedure would not materially affect the patient and that continued sedation and intermittent positive-negative ventilation would probably be required for treatment. Marked central stimulation was expected with the massive dose of adrenaline, and if the patient had been allowed to wake the probable restless agitated state with raised venous pressure and inadequate tissue perfusion would have been undesirable. Adequate pulmonary ventilation with an oxygen-rich mixture seemed essential and this could easily be provided with the anaesthetic technique in use.

It is not proposed to discuss the possible effects of very large doses of adrenaline, as much of this would be pure speculation. Hypertension, tachycardia, and vasoconstriction were the presenting symptoms in this case, and treatment with a ganglion-blocking drug (trimetaphan) was aimed at rapidly reducing the systolic blood pressure.

It is difficult to explain the prolonged period of hypotension that occurred. In view of the expected duration of trimetaphan it is not likely to be a factor. One might argue that its use was continued longer than necessary, but in view of the persisting skin vasoconstriction this also seems unlikely. Our knowledge of the relative duration of action of the alpha and beta effects of the catecholamine is not such as to throw any light on the subject, but the answer may well lie therein.

Current Practice

Road Safety Act, 1967

[BY A SPECIAL CORRESPONDENT]

The purpose of this article is to review changes in procedure which may be necessary when doctors are called to the police station to examine or to take specimens of blood from drivers detained by the police. In 1965 the British Medical Association published a report, "The Drinking Driver,"¹ which sets out a recommended procedure; and reference to this publication, which is widely used by doctors called to advise the police, will be given in this article.

Changes in the Law

The main change is that new offences have been created² of driving, attempting to drive, or being in charge of a motor vehicle while the proportion of alcohol in the blood is in excess of 80 mg./100 ml. The existing offences relating to driving under the influence of alcohol which are found in the Road Traffic Acts, 1960 and 1962, are retained, and the advice contained in *The Drinking Driver* will continue to apply to procedures under those Acts. The older legislation will generally apply where the driver is under the influence of drugs other than alcohol, though it will remain possible for a driver to be convicted under these Acts where it can be proved that his ability to drive properly for the time being is impaired by alcohol even though the blood alcohol concentration (B.A.C.) is below 80 mg./100 ml. It seems likely that in practice the police will have decided the Act under which they propose to proceed by the time the doctor is called to take the statutory specimen of blood. Even in cases where the driver agrees to plead guilty under the Road Traffic Acts, 1960 and 1962, the police cannot be certain that the driver will not afterwards change his mind. Much will depend, therefore, on the procedure adopted by each local police authority.

It is early to give an opinion on the changes in procedure which will follow the introduction of the new Act. Under previous Acts a body of case law grew up on various aspects of procedure and it may be some months before more positive guidance can be given on some of the points covered in this article.

Clinical Medical Examination

B.M.A. reports have always emphasized the need for a comprehensive medical examination of drivers suspected of being unfit to drive as a result of having taken alcohol. The main purpose of such examination has always been the exclusion of illness or injury. These recommendations were based on the assumption that drivers would continue to be detained by the police on a selective basis—that is, only those drivers who showed evidence of intoxication or had been involved in an accident would be arrested by the police. The Government White Paper³ points out that even after 1962 (when the stronger criterion of impairment of driving ability was introduced) the police have rarely proceeded in cases where the B.A.C. is less than 150 mg./100 ml.

The new Act introduces an element of random selection in that a driver who exhibits no symptoms of alcoholic intoxication, and who has not been involved in an accident, may be detained by the police and be required to give a blood sample—for example, where he has committed an infringement of the traffic regulations and he gives a positive breath test upon being stopped by the police. In these circumstances a comprehensive medical examination will not be necessary

unless the doctor called in by the police to obtain the blood specimen has reason to believe that it is desirable to exclude the presence of illness or injury in the circumstances of the particular case. If the police have not requested an examination, but the doctor feels that it is necessary, he should tell the officer in charge of the case so that facilities for an examination to take place may be provided.

The paragraphs in *The Drinking Driver* relating to consent continue to apply, with the exception that the purpose of the examination (which must be explained to the driver) is limited to excluding illness or injury and to enabling the doctor to advise the police whether the driver is fit to be detained. The rule that the driver must be informed that he is entitled to request an examination by a doctor of his own choice was formulated to enable the driver to call his own medical evidence on the issue of fitness to drive. The position has now changed. Under the new Act evidence of fitness to drive based on clinical medical examination is no longer relevant. However, if the driver claims he is suffering from illness or injury and asks for his own doctor every attempt must be made to make the necessary arrangements. Furthermore, the doctor called by the police should bear in mind that in some cases it may be desirable to contact the driver's own doctor (with the consent of the driver) in order to assist in arriving at a diagnosis. This is particularly important where there is reason to believe that the driver may have been under recent active medical treatment.

The Act authorizes the police to carry out a breath test on drivers under certain conditions and provides penalties for drivers who refuse. Though the breath index tubes are relatively crude instruments, they may nevertheless provide useful diagnostic information—as, for example, where the symptoms of intoxication are quite inconsistent with the concentration of alcohol indicated by the tube. In such cases the possibility of the driver suffering from unsuspected illness, injury, or the effects of other drugs must be considered very carefully. Breath tests for alcohol have been available for 30 years or more and it is surprising that they have not been introduced into casualty departments of hospitals. It is not unknown for a suspected "drunk" to be turned away from a casualty department only to die later from an unsuspected head injury.

The driver who refuses unreasonably to take a breath test in circumstances where the police are entitled under the Act to require one is subject to penalties. It follows that medical evidence may be called by the defence when the driver claims on medical grounds to be unable to take the test. It has been found that patients with fairly severe degrees of cardiorespiratory failure are able to take the test without ill consequences. The Government White Paper³ suggested that asthmatics might be unable to take the test, but it should be borne in mind that asthmatics are used to breathing out against resistance and can reasonably be expected to take the test if they are fit enough to drive a car.

Urine Samples

The Drinking Driver recommended that as part of the examination a specimen of urine should be obtained for the purpose of testing for albumin, sugar, etc., but that the police should be consulted before such a specimen is taken in order not to compromise the procedure for taking statutory specimens under the Road Traffic Acts. In practice the statutory specimen under the 1962 Act has nearly always been of urine, and it could be used also for determining the presence of drugs other than alcohol. Under the new Act it is expected that the statutory specimen will nearly always be of capillary blood. Analytical techniques are not sufficiently advanced to determine the presence or quantities of drugs other than alcohol from such small specimens. A urine specimen should be obtained if it is suspected that the driver is under the influence of drugs other than alcohol.

It was the custom in most areas under the 1962 Act for doctors to provide the police with a certificate of opinion at the end of the medical examination. A draft certificate is set out in *The Drinking Driver*, but some of the information which it contains will be inappropriate under the new Act. The certificate should be limited to stating the name of the driver, the date, time, and place of examination, and whether or not the driver is fit to be detained by the police. If no certificate is requested by the police a note of these items should be made by the doctor at the time and retained by him. This certificate is quite distinct from the certificate that blood has been taken. There has been some doubt about the powers of the police to detain drivers under the 1960 Act in circumstances where the driver appears to be unfit to drive home. On occasion drivers have been released from the police station only to be involved in an accident shortly afterwards. The new Act authorizes the police to detain a driver until such time as his B.A.C., as determined by a breath test, is below 80 mg./100 ml. This power is discretionary and is unlikely to be exercised where arrangements can be made for the driver to be driven home.

Sampling Methods

The Road Traffic Act, 1962, permits blood, breath, or urine to be used in support of a prosecution for impaired driving ability. No regulation was ever introduced authorizing the use of breath under that Act, and the new Act withdraws the Minister's power to issue such a regulation. The "screening" breath tests authorized under the new Act are only crude indications of the B.A.C. and they cannot be used in court as evidence of the B.A.C. being in excess of 80 mg./100 ml. Their only function is to assist the police and to determine whether or not the driver can be required to give a specimen of blood.

The Drinking Driver recommended in favour of blood in connexion with a statutory blood alcohol concentration, but the new Act permits the driver to give a specimen of urine if he refuses to allow a specimen of blood to be taken. The driver who refuses to allow blood to be taken must give two specimens of urine within an hour, and if he is unable to do this the obligation to allow a specimen of blood to be taken returns. The first specimen of urine is discarded and analysis is carried out on the second specimen alone. No doubt anticipating the use which would be made by the defence of the detailed objections set out in *The Drinking Driver*, the Act states that a urine alcohol concentration of 107 mg./100 ml. shall be deemed to be equivalent to a B.A.C. of 80 mg./100 ml., thereby preventing any argument in court on the conversion factor which ought to be used in the particular case. As the factor is based on a mean figure, the driver who opts for urine has an even chance of benefiting, thereby providing yet another example of what has been termed the sporting theory of English justice. Under the 1962 Act the analyst is required to state on his certificate the equivalent figure for blood in the case of urine

specimens. Under the new Act no corresponding figure for blood will be given on the certificate. It is expected that police will obtain the urine specimens in cases where the driver refuses to allow blood to be taken.

Upon arrival at the police station the driver must be offered a further breath test by the police, and if this test proves to be negative the police cannot require him to allow a specimen of blood to be taken under the new Act. The consequences of failure, without reasonable excuse, to allow a specimen of blood or urine to be taken are severe under the new Act. Such refusal constitutes a separate offence, the penalties of which are the same as those for the substantive offence. The effect of refusal where the police are proceeding under the previous Acts remains the same—namely, that the fact of refusal will be given in evidence by the prosecution.

Haemorrhagic Disorders

Medical evidence may be called by the defence where the driver refuses on medical grounds to give a sample of blood, but there are very few medical conditions in which it might be dangerous for the driver to allow a sample of capillary blood to be taken. Notwithstanding any consent obtained by the police, the doctor must satisfy himself that the driver consents to a specimen being taken and that the driver understands what is involved. If it is thought to be in the interests of the driver that his arm or head should be steadied while the specimen is taken the reason must be explained to the driver and his consent obtained. There must be no suspicion of the specimen being taken under forcible physical restraint. It is expected that capillary blood will be the specimen of choice under the new Act, and during the past few months police authorities throughout the country have been conducting courses for doctors on the correct technique. Sealed packs containing lancets, plastic labelled cups with airtight lids, and dressings are being supplied to police stations by the forensic science laboratories. Doctors should use the packs supplied and should follow any recommendations contained in them. Three of the cups must be half filled with the blood specimen and the lids firmly replaced, and the cups shaken to ensure admixture with the preservative and anti-coagulant which are contained in the cups. The doctor must then label the cups and complete a statutory certificate stating that he took the specimen with the consent of the driver. It is important that a non-alcoholic solution is used to clean the skin. The police will be responsible for the disposal of the specimens and for offering part of the specimen to the driver.

Evidence in Court

The Act is so drafted that the opportunities given to the defence to discredit the evidence produced by the prosecution are reduced considerably as compared with previous Acts. The wording of the Act rules out any argument based on individual variations in the metabolism of alcohol. It seems that the question will arise under the new Act only in cases where the driver is prosecuted for being "in charge" and the defence seeks to raise the defence (and therefore has to prove) that there was no likelihood of his driving so long as he remained unfit to drive or so long as there was any probability of his B.A.C. being above 80 mg./100 ml. Under the previous Acts he was also required to prove that he had not driven since he became unfit to drive, but the new Act has repealed this and provides that the driving prior to stopping can be ignored for purposes of the "in charge" offence. This should have the desirable effect of encouraging drivers to stop driving if they feel they are affected by alcohol instead of taking a chance on getting home. It is expected that in future the main oppor-

tunity available to the defence will be to question the sampling methods, the identification, transportation, and preservation of the specimens and the analytical method. Accordingly, it will be of paramount importance for doctors to follow explicitly the instructions which are provided by the police for obtaining specimens under the new Act. Clinical medical evidence of unfitness to drive is not an issue under the new Act. The new Act allows the doctor's evidence relating to the taking of the specimen to be given by certificate, which must be served on the defence at least seven days before the hearing. The doctor will not normally be required to attend unless the defence gives notice.

Hospital Cases

The Ministry of Health has sent out a circular which explains the procedure to be adopted when drivers attend a hospital.⁴ It is important to note that the doctor in charge of the case may object not only to the specimen being taken but also to the requirement to provide a specimen being indicated by the police to the patient. The police must arrange for their own doctor to take the necessary specimen of blood and he must take his own equipment with him. Apart from providing facilities of reasonable privacy for the sample to be taken the hospital authorities play no part in the procedure.

Conclusion

The Drinking Driver drew attention to the need for police authorities to appoint doctors on a retaining basis in order that expert medical advice and assistance would be speedily available to the police. The reluctance of many police authorities to do this and the tendency to rely on any doctor who happens to be available has long been a source of irritation and has certainly not been in the interests of justice. It will be impossible to administer the provisions of the new Act unless doctors are freely available to take specimens of blood and to advise the police. Fortunately, the Home Office has already issued two circulars to police authorities drawing their attention to the pressing need to make the necessary arrangements before the Act comes into force, and agreements are being reached between local B.M.A. representatives and local police authorities (who are autonomous in these matters) on the fees and allowances which will be paid to doctors called by the police.

Fallacies in Four Fevers

R. S. ILLINGWORTH,* M.D., F.R.C.P., D.C.H., D.P.H.

Among other fallacies habitually copied from one textbook to another or lingering in the minds of practitioners as a relic of treatment of the past, because their validity has never been questioned, are those concerning the common infectious diseases of childhood. This paper concerns four common infections—measles, German measles, chicken-pox, and mumps. The fallacies to be discussed concern confinement to bed, quarantine, isolation, undue absence from school, dietary restrictions, and the use of medicines.

Confinement to Bed

When considering the value of any line of treatment, including the administration of any drug, one should always think of three questions: What good may it do? What harm may it do? What harm may be done by not giving this treatment?

It is the practice of many doctors to confine children to bed for any of a wide variety of conditions such as abdominal discomfort, headache, a sore throat, a slight rise of temperature, a cold, or diarrhoea without any apparent reason. The fallacy of such treatment has been discussed by me several times,¹⁻⁴ and subsequently by Jolly.⁵ If a child feels well enough to be up—even merely sitting in a chair by the fireside—and wants to be up, even if his temperature is raised, it is very difficult to think of any reason for confining him to bed. There are possible exceptions: infectious hepatitis, the preparalytic stage of poliomyelitis, and the first few days of rheumatic fever. I can certainly see no reason why it should be thought likely that a child with a sore throat would recover more quickly if he sits up in bed than if he sits up in a chair reading a book in front of the fire. I am unable to think of any physiological mechanism which would make it likely that he would recover more

quickly if he sat on a bed than if he sat on a chair. In hospitals which I have visited in many countries of the world, including Russia, all children are kept in bed. In one hospital I saw a ward full of children with behavioural problems, and in another a ward full of children with epilepsy, and in both cases all children were kept in bed throughout their stay in hospital.

So children with measles, rubella, chicken-pox, or mumps should not be kept in bed if they want to get up. A child in the febrile stage of measles before the rash appears may well prefer to stay in bed. I can see no reason otherwise why children with these conditions would be harmed by being out of bed. There is no physiological or pathological basis for a belief that complications, such as orchitis in mumps, would be more likely if the child were out of bed.

I can see many reasons why confinement to bed may be harmful. It bores children. They sleep less well if they have been confined to bed. The adverse physiological and pathological consequences of bed rest have been well described in the excellent book by Browne,⁶ who aptly wrote that "the bed is often a sign of our therapeutic inadequacy, rather than a therapeutic measure deserving of praise. The bed is the non-specific treatment of our time, the great placebo."

Quarantine

Thanks largely to the work of Smith at Rugby⁷ it is now widely recognized that children should not be quarantined for the common infectious diseases. Quarantine was not successful in the prevention of infectious disease in the past. Ninety per cent. of children acquired measles by the age of 14, 70% acquired chicken-pox, and 50% acquired rubella and mumps. If healthy contacts are prevented from going to school they will assuredly mix with their school fellows after school hours. In

* Professor of Child Health, the University of Sheffield.

the past children were placed in quarantine even if they had had the infection in the past. There is no truth in the idea that contacts can carry the infections of measles, German measles, chicken-pox, or mumps to school without themselves suffering from them. It was quite irrational to isolate contacts throughout the incubation period of infectious diseases. For instance, the usual incubation period of mumps and rubella is about 16 to 18 days. Contacts who are going to acquire the disease cannot be infectious for at least the first 12 days after exposure.

Smith wrote that after 16 years' experience of 75 outbreaks of infectious disease at Rugby School there was no instance in which the originator knew how he had acquired the infection. In the same period 203 boys who had been exposed to infection were allowed back to school, and only one acquired the expected disease at school. There were no secondary cases. If strict quarantine had been enforced 4,224 days would have been lost.

Quarantine for these infections is outmoded.^{8 9} This does not mean that there should not be sensible surveillance—that a careful eye should not be kept on a contact after a suitable point in the incubation period.

Isolation

It is usually futile to attempt to isolate an infected child from others in the family. By the time the diagnosis has been made the other children have already been exposed to him at the most infectious stage of the illness. In any case, there is much to be said for children acquiring the infection in childhood rather than later. Mumps is rarely complicated by orchitis before puberty, so it is better for boys to acquire mumps before then, so that they do not acquire mumps with the risk of orchitis later. It is desirable for girls to acquire rubella before pregnancy. I believe (rightly or wrongly) that adults are liable to be more ill with the common infectious diseases than children are.

It is most regrettable that there are still infectious disease hospitals which do not allow parents to visit their children with these infections, or which, worse still, allow them to see their children through a glass partition—an infuriating and thwarting experience for a small child. The rationale of such isolation measures escapes me. The harm done by them is obvious.

Keeping the Child Off School

At any one time about 10% of schoolchildren in England and Wales are absent from school. Only a small proportion of these are absent for any good medical reason.^{10 11} In the case of the four common infectious diseases many children are kept away from school for much too long a period. The duration of infectivity of these four infections is shown in the Table.

Duration of Infectivity of the Common Infectious Diseases

Measles		Five to six days before the rash until six days after the appearance of the rash if the child is afebrile
Rubella		One day before the rash until two days after the appearance of the rash
Mumps		Two days before the swelling of the parotid gland until the swelling has subsided
Chicken-pox		One day before the rash until six days after the appearance of the rash

It would be interesting to see figures for the mean duration of absence from school for these conditions—and the differences between children from one area of a city or town and those from another.

Obviously no child should go back to school until he is fit, but prolonged absence of a well child from school is altogether wrong.

Dietary Restrictions

There are still some doctors who, without thinking, prescribe a "light diet" for children with infections. Provided that their appetite is unimpaired I cannot see any reason for such a diet.

Medicines

For chicken-pox and rubella there is no indication for any medicine. There is no need to prescribe a lotion for the rash of chicken-pox. For an occasional case of mumps with severe pain a sedative may be indicated, but no medicine should be given otherwise. For measles, unless there is a complication such as otitis media or pneumonia, both of which demand the use of antibiotics, there is no indication for medicine. Investigation¹² has shown that the prophylactic use of an antibiotic in measles does nothing to reduce the incidence of complications. There is no point in giving the child cough medicine. It will achieve nothing. How much money is spent in England and Wales each year on the totally unjustifiable prescription of medicines for children with these four fevers?

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Antibiotics in Measles

Q.—The reasons given by some doctors for the administration of antibiotics as a routine in all measles cases are: (1) It cannot do any harm; (2) it satisfies the child's parents, who expect it; (3) other doctors do so. What are the arguments against this?

A.—Apart from the general undesirability of treating conditions with agents known to be ineffective, there are four reasons why antibiotics should not be given:

(1) It is certainly not true that they are harmless.¹⁻³ The philosophy that antibiotics can do no harm and might do some good underlay the fatal "grey syndrome" in children given prophylactic chloramphenicol.⁴

(2) The prevalence of antibiotic-resistant organisms is proportional to the amount of antibiotic used.⁵ Widespread prescribing of antibiotics for virus infections which cannot respond to them can only increase the chances that initially sensitive bacterial infections will become inaccessible to treatment.

(3) There is a temptation when giving drugs for inadequate reasons to avoid side-effects so far as possible by giving inadequate doses. In the case of antibiotics, apart from facilitating the emergence of resistance, this may suppress any bacterial superinfection just enough to make the diagnosis, and hence the treatment, exceedingly difficult.

(4) Antibiotics are not cheap, and there are more useful ways of adding to the drug bill.

B.C.G. and Tuberculin-positive Subjects

Q.—What, if any, is the danger in giving B.C.G. to a subject who is tuberculin-positive after a healed primary infection?

A.—There are so far as I know no reports of systematic studies concerning this subject in man, but serious general or focal reactions are improbable. There might occasionally be a mild transient fever, as when a large dose of tuberculin is given subcutaneously to a sensitive subject, and theoretically there might be a focal reaction at the site of the old primary complex. The likelihood of reactivation or dissemination of tuberculosis seems extremely small, though the possibility is difficult to exclude.

The most constant complication of giving B.C.G. to a tuberculin-positive subject, especially anyone sensitive to a small dose of tuberculin, is the occurrence of a severe accelerated local reaction—the classical Koch phenomenon. Ulceration, probably, substantially larger than that occurring after vaccination of an uninfected individual, could be expected within a few days and might prove slow to heal, leaving a larger area of scarring than occurs after the usual B.C.G. vaccination.

The situation in respect of the use of B.C.G. without preliminary tuberculin testing has been summarized by the W.H.O. Expert Committee on Tuberculosis in its eighth report¹ thus: "These studies have not demonstrated local, regional, focal, or general complications detrimental to the health of the tuberculin reactors among the vaccinated individuals. . . ."

Staphylococcus and Erythema Nodosum

Q.—Is it possible to get erythema nodosum with a *Staphylococcus pyogenes* infection?

A.—So far as I am aware attention has not been particularly drawn to staphylococcal infection as a cause of erythema nodosum. On the other hand, while some causes (streptococcal infection, sarcoidosis, and, formerly, tuberculosis) are much more common than others, it seems that erythema nodosum may develop in suitably sensitive subjects in response to a wide variety of stimuli. Among those identified have been viral, bacterial, and fungal infections, drug sensitivities, neoplastic diseases, sarcoidosis, ulcerative colitis, appendicitis, bronchiectasis, and other assorted states.¹⁻³ It would be surprising in the circumstances if *Staphylococcus pyogenes* did not sometimes excite a similar response.

It is an interesting feature of erythema nodosum that even when it has followed epidemics of viral⁴ or fungal infections, which attack both sexes equally,⁵ it has still appeared almost exclusively in the female.

Sudden Loss of Vision

Q.—What might be the condition causing sudden loss of vision in one eye when there are arteriosclerotic changes in the fundus and a picture of venous thrombosis of all the branches of the central vein (swollen, dark, tortuous vessels) but no haemorrhages such as are usually found in typical thrombosis?

A.—It is difficult to give an opinion without further details. Sudden complete loss of vision strongly suggests an occlusion of the central retinal artery. The central vein lies very close to the artery in the optic nerve and might be affected by an inflammatory reaction. If the central artery remains occluded the retinal arteries will be narrowed and there will be retinal oedema with a cherry-red spot at the macula.

If the retinal arteries are reasonably normal a condition such as giant-cell arteritis (tem-

poral arteritis) should be considered. Carotid artery disease is another possibility, but preliminary attacks of amaurosis rather than sudden loss of vision are usual.

Medical Equipment for Explorers

Q.—What medical equipment and drugs should four laymen take on a voyage by sailing-boat which might last three months? Are there any books on the treatment of simple illnesses and accidents suitable for travellers?

A.—The following equipment and drugs should meet the case:

Medical Equipment.—Scissors, 5 in. (12.7 cm.) straight pointed, 1 pair. Dressing forceps, 5 in., 2 pairs. Safety pins, assorted, 12. Crepe bandages, 3 yds. long by 3 in. wide (2.7 m. by 7.6 cm.), 2; 3 yds. long by 4 in. wide (2.7 m. by 10.2 cm.), 2. Elastoplast, 3 in. (7.6 cm.) wide, two-way stretch, 2 rolls; 3 in. wide (one-way stretch), 2 rolls. Zinc oxide adhesive plaster 10 yds. long by 1 in. wide (9.1 m. by 2.5 cm.), 4 rolls. Dumb-bell butterfly closures, 1 tin of 100. Gauze swabs, 2 sq. in. (12.9 sq. cm.), 100. Cotton-wool, 1 lb. (0.454 kg.). Sofra tulle, 2 tins. Glacier cream, greasy (Savory and Moore), 4 tubes.

Drugs.—Acriflavine lotion B.P.C. 1/250 dilution for use in 1/1,000 dilution. Cetrimide and chlorhexidine solution 250 ml. for use in 1/100 dilution. Ampicillin capsules B.P. 250 mg., 100. Aspirin soluble tablets B.P. 600 mg., 200. Chlortetracycline eye ointment B.P., 2 tubes. Codeine phosphate tablets B.P. 60 mg., 50. Dimenhydrinate tablets B.P. 50 mg., 200. Hydrocortisone lotion B.P.C. 1%, 250 ml. Omnipon tubonic ampoule syringes 20 mg. (1 ml.), 6. Pentobarbitone tablets B.P. 100 mg., 50.

The proceedings of the symposium on exploration medicine, held on 25-26 October 1962 by the Royal Geographical Society,¹ should prove useful.

Notes and Comments

Ranges of Forced Expiratory Volume.—Dr. J. J. SEGALL (Chest Clinic, Whittington Hospital, London N.19) writes: "With reference to the answer to this question ('Any Questions?' 9 September, p. 668), your expert is surely mistaken in giving the 95% confidence limits as one instead of two standard deviations on either side of the mean. In practice two standard deviations below the mean F.E.V.₁ for sex, age, and height results in too low a limit of normal. For this reason it is preferable in clinical work to regard the lower limit of normal as 85% of the predicted (i.e., average) value, as recommended by the American Committee on Rating of Mental and Physical Impairment."

OUR EXPERT replies: Dr. Segall is quite correct that the 95% confidence limits are two standard deviations: One standard deviation includes only approximately 60% of the community.

Book Reviews

Postgraduate Medical Federation: Early Years

The British Postgraduate Medical Federation. The First Fifteen Years. By Sir Francis Fraser, M.A., M.D., F.R.C.P., LL.D. (Pp. 69+vii. 15s.) London: Athlone. 1967.

Recent developments of medical education in this country lend particular interest to this short monograph on the early years of the Postgraduate Medical Federation by the distinguished physician who was appointed its first director in April 1946. Francis Fraser was well equipped for the responsibility; he had been professor of medicine at the Hammersmith School and Hospital since its foundation in 1934 and had contributed much to the high reputation it so quickly won. His ability and integrity were everywhere acknowledged and in December 1947 the University of London granted to the new Federation the status of a "School of the University" in respect of its facilities at Hammersmith. Within a few years several Institutes representing special subjects were included in the fold and their academic standards were high—by 1960 there were no fewer than 30 professors, of whom five had

been elected Fellows of the Royal Society.

To-day medical institutes are springing up all over the country to provide graduate instruction and facilities for research, and they have the cordial support of the universities, the regional hospital boards, and local industry; together they constitute one of the most promising and valuable developments in the National Health Service and they owe a great deal to the experience gained by the Federation Fraser did so much to shape. How rapid progress has been is revealed by a most interesting account of what had been attempted before the establishment of the Hammersmith Hospital School.

Jonathan Hutchinson was the pioneer. In the closing years of the nineteenth century "he devoted each Wednesday afternoon to a widely attended clinic held at his house for doctors from any part of the world who happened to be in London." William Osler

followed with a Medical Graduates College which became the Fellowship of Medicine. The London undergraduate schools had a Postgraduate Association which dissolved in 1913, and a few non-teaching hospitals provided sporadic courses. Otherwise there was little postgraduate teaching in England. In 1925 Neville Chamberlain while Minister of Health appointed a committee (with himself as chairman) to draw up "a practical scheme for postgraduate medical education centred in London." That committee reported in 1930 and, taking advantage of the Local Government Act of 1929, recommended the establishment of the centre at Hammersmith.

Fraser gave the last years of his life to this book and died two weeks after completing the script. It is a simple record of difficult work well done which has already had wide and enduring influence. In one respect it is incomplete; there is hardly a word about the significant part played by the author. Those who knew Francis Fraser will understand the omission; he never sought a public image—the work itself was sufficient and the only thing that mattered.

ARTHUR THOMSON.

Radiation and Chromosomes

Human Radiation Cytogenetics. Proceedings of an International Symposium held in Edinburgh, 1966. Edited by H. J. Evans, W. M. Court Brown, and A. S. McLean. (Pp. 218. 70s.) Amsterdam: North-Holland. 1967.

This is a valuable collection of papers dealing with a circumscribed subject, so that any reader interested in one will be interested in all. In J. Visfeldt's words, "the principal object of these studies has been the classical desire to establish the dose-effect relationship. If this could be attained by determining chromosome aberration yields from humans irradiated in vivo the basis of human biological dosimetry would be obtained."

There are several papers about techniques, particularly the culture of lymphocytes from blood, and two contributions on the automation of chromosome analysis. There follow a few papers on the lymphocyte lifespan; if a lymphocyte can carry an "unstable" chromosome lesion dating back to irradiation many years before, this may be a vital clue to the mechanism of "immunological memory" (P. H. Fitzgerald and P. C. Nowell). Finally, there is a whole series of papers covering the chromosomal abnormalities found in persons exposed to ionizing radiations from occupational, therapeutic, accidental, and military causes. Not unexpectedly, the Edinburgh group are strongly represented in this section, and there is a noteworthy contribution from Ishihara and Kumatori on the fishermen irradiated by fall-

out from Bikini. In their series there is even a suggestion of formation of persistent abnormal clones, and the discovery of cells from several cases with a Ph¹-like deleted chromosome is of great interest in connexion with the origin of chronic myeloid leukaemia.

The "classical desire" has not been entirely fulfilled, and variations in technique and interpretation have resulted in large differences—for instance, the incidence of rings, dicentric, and fragments in normal controls is 0.01% according to A. B. Bloom and his collaborators in Japan, but 0.8% according to K. E. Buckton and her colleagues in Edinburgh. Some of the differences can be resolved by the uniform use of a 50-hour incubation period, so that all cells are in their first division.

The possibility of using chromosomal defects as a "biological dosimeter" depends on the scoring of very large numbers of cells in order to show statistically significant differences. The editors optimistically say that "developments will be all the more rapid when facilities for the automatic analysis of cells by computer become available—a prospect which may well be realized in the near future." The automatic analysis of a selected perfectly spread metaphase is already well within sight, as D. Rutovitz's contribution beautifully shows; but it could be a far cry from this to the analysis of hundreds of cells in average material.

The editors and publishers are to be congratulated on the rapid publication of this volume, which includes much material not obtainable elsewhere.

A. I. SPRIGGS.

Surgery of the Hand

Hand Surgery. By J. Edward Flynn, M.D. (Pp. 1095+xvi; illustrated. £15 8s.) Edinburgh: E. & S. Livingstone. 1966.

This is a reference book, weighing more than 4½ lb. (2 kg.), which is a sizable volume even for hand surgery. As Sumner Koch notes in a detailed and informative preface, the method of presentation, "popular in the United States, results from the collaboration of a number of men who are specialists in their fields. The editor presents their contributions, usually with comment and change." It is a style which is apt to lead to overlapping of subject material and repetition of detail, but there is a 20-page index which helps to make up for this defect.

The editor has chosen 57 specialists to help him in his presentation of hand surgery; six of them are from Europe. The work is therefore comprehensive of current opinion and teaching. Some of the chapters are outstanding monographs, but others stray unnecessarily far up the arm—to the shoulder joint, or deal surprisingly fully with general medicine—such as tetanus. The omission of a chapter on leprosy and the inclusion of one on disability assessment and compensation in the United States gives the book a parochial stamp out of place in a treatise which must surely have been intended for world circulation.

Having overcome these personal objections to style and choice of material, there is a great deal of interesting and instructive information and experience presented here. In the first chapter H. C. Marble presents

a history of hand surgery, and this is followed by a comprehensive account of the anatomy and kinesiology of the hand by E. P. Kaplan. Hand trauma is covered in about 30 chapters, which include an original contribution on primary and secondary repair of flexor and extensor tendon injuries by Claude Verdan, of Switzerland, and a thoughtful and imaginative discussion of tendon transfers in the forearm by Paul Brand.

Vascular disorders, infections, contractures, and tumours each have several interesting chapters devoted to them. It is surprising, however, that such an important practical subject as rehabilitation of the injured hand gets only sketchy treatment in a few columns in a book of this size.

D. MACG. JACKSON.

Health Services in the U.S.A.

Health is a Community Affair. Report of the National Commission on Community Health Services. (Pp. 252+xiv. 40s.) London: Oxford University Press. 1967.

The American Public Health Association and the National Health Council—the sponsors of this book—created in 1962 the national commission to study, recommend, and report to the people of America on the present and future requirements of the health services.

A long list of members of the commission contains the names of doctors, lawyers, and others who together provide a body of high authority and wide experience. This work ranges over the whole of the health field and provides detailed information of the deficiencies and what are thought to be the needs in America. There is also a mass of stimulating opinion and much guidance for future “programs”—some remedial and some drastic. The United States and this country obviously have problems in common in relation to the health services but in many ways the approach to their solution differs—arising, no doubt, from the differences between their political and economic backgrounds.

Some of the statements in the book are challengeable—for example, “We do not know how to purify air for all the people just before we breathe it. People are in the same relative position with regard to air pollution as are fish with regard to water pollution.” This is not really the case. In both Britain and America we know perfectly well how to deal with air pollution—the trouble is that we fail to do it—and in this respect we are like the poor fish. We know how but we have inadequate drive and vigilance in matters of clean air.

The following statement will clearly find a responsive reaction here: “In addition, each community must be able to enter the recruitment competition with the knowledge that financial reimbursement for all kinds of health personnel will be competitive with that received by people performing comparable jobs in the community.” America, it appears, suffers as we do.

A possible future reorganization is envisaged. “Local community leaders should be encouraged to begin thinking in terms of clusters of cities, towns, and related rural areas which make natural, or at least organizationally feasible and defensible,

regions for improving the health of the area.” This is the same concept apparently as the proposal supported by the majority of the medical profession here—larger administrative regional units. The recommendations on health services and jurisdictional areas will provide food for thought for those who are interested in the work of the Royal Commission on Local Government.

Another recommendation is that every individual should have a personal physician who “will have knowledge of and access to all the health resources of the community—social, preventive, diagnostic, therapeutic, and rehabilitative—and will mobilize them for the patient.” This is a completely acceptable statement, but it may be a surprise to some people that this position has not been reached already in the United States.

The dust cover states that the book is written in a non-technical and readable fashion. Non-technical certainly, and heavy going sometimes, but it should nevertheless be read.

C. METCALFE BROWN

Indulging and Abstaining

Clinical Dietetics and Nutrition. With Special Reference to Tropical Foods. By F. P. Antia, M.D.(Bom.), M.R.C.P.(Lond.), M.S.(Ill.). (Pp. 563+ix. 42s.) London: Oxford University Press. 1967.

The aim of this book is to provide students and practitioners with the knowledge of clinical nutrition and dietetics needed for general and hospital practice. The slant is towards practice in India and the Far East, but the book has been written with the needs in mind of practitioners in any part of the world, tropical or temperate.

There are four parts to the book. The first is composed of sections dealing with substances needed for nutrition such as proteins, vitamins, and minerals. The amounts needed for health and levels in body fluids and tissues are given together with basic facts concerning the role of each in physiology and pathology. The effects of deficiency are described together with the way to supplement a diet with the substance, and where appropriate the way to prepare a diet containing little of it. The well-written section on sodium is an example of the latter. In the second part various foods are described in some detail, not only as regards their constituents and the preparations made from them, but also the diseases they may benefit, cause, or transmit. All this is very well done. The third part consists of descriptions of the dietetic management of many diseases, including peptic ulcer, hepatic cirrhosis, kwashiorkor, cardiac failure, and hypertension. The fourth section is composed of tables of food values, recommended allowances, heights, and weights.

The work is remarkably comprehensive, the information accurate and very practical. It will without doubt provide an invaluable source of information enabling better management and understanding of disease. Physicians tend to be vague when advising patients about diet; partly because detailed instruction in this field is not often given in medical schools, partly because in few books is the necessary information drawn together

conveniently, and partly because knowledge in many parts of the field has advanced rapidly and it is difficult to keep up to date. Use of this book will take care of all these aspects of the problem. It deserves high praise and success.

A. W. WOODRUFF.

Havelock Ellis's Life

My Life. New edition. By Havelock Ellis. (Pp. 614+xli; illustrated. 45s.) London: Neville Spearman. 1967.

Havelock Ellis (1859–1939) is widely known as the author of *Studies in the Psychology of Sex* and other books on kindred subjects. His writings were his life-work, and yet they are hardly mentioned in this detailed, intimate, and often obscure narrative.

At the age of 4 he was first touched by the mystery of woman. Their nurse was wheeling the baby in the perambulator and he was alongside. Unexpectedly she stood still and he heard a sound like a stream of water descending. His mother behaved in exactly the same way several times when walking with him in the park. From the fact that seeing a woman urinating aroused him sexually, he detected in himself a slight abnormality, the germ of a perversion.

He was not robust, and at 16 his father, a sea captain, took him to Australia. He taught in private schools near Sydney for four years and then, quite suddenly, he decided to become a doctor. Returning to London he entered St. Thomas's Hospital, and after a halting career qualified as L.S.A. He held one or two posts as an assistant and then abandoned medical work in 1884. But he remained a member of the B.M.A. all his life.

A remarkable feature of this autobiography is the omissions. Thus Freud's name is not mentioned, though he and Ellis corresponded for 35 years. Eventually misunderstandings appeared and they parted. In his twenties Ellis and Olive Schreiner became close friends. Her letters to him run into thousands, all preserved in numbered bundles. He refused her request to return them, as he read and reread them. She would not have wanted them to be published; nevertheless after her death he made a selection of them available when her life was being written. He held that one who was dead, whose sensitiveness could no longer be hurt, is not the fit arbiter of what should or should not be published.

Marriage brought Ellis and Edith, his wife, joy and happiness. It succeeded, he believes, because they were often apart: she preferred Cornwall and he London. Edith had a succession of lesbian friends and he accepted this situation without reservation. He himself had intimate friendships with several women friends. This hurt Edith grievously and she attempted suicide twice. After one crisis she obtained a legal separation. But “separation” is perhaps a misnomer, for their way of life was not altered and their mutual devotion remained constant till her death in 1916.

Alan Hull Walton's admirable introduction shows Ellis as a pioneer. The rumours that he was impotent and a homosexual are denied. These may have spread because

Ellis had written a book on homosexuality, and had "inadvertently married a lesbian." In the foreword Françoise Delisle writes: "His autobiography stops at his wife's death, leaving twenty-three years untold." Ellis speaks of "my beloved Françoise—whose devotion and sympathy enfold me in radiance, so that sometimes I am almost disposed to begin the narrative of a second and later life."

E. A. BENNET.

"Carleton"

Carleton's Histological Technique. 4th edition. Revised and rewritten by R. A. B. Drury, M.A., D.M.(Oxon), F.C.Path., and E. A. Wallington, F.I.M.L.T. (Pp. 432 + ix; illustrated, 60s.) London: Oxford University Press, 1967.

This new edition of an old friend will be a welcome addition to the laboratory bookshelf, or more probably to the bench. Dr. Drury, who collaborated with the late H. M. Carleton in the 1957 edition, has now revised and extensively rewritten the fourth edition with the help of Mr. Wallington.

The basic pattern remains unaltered but two changes are welcome; much more space is devoted to the theory of technology and the methods are now grouped according to the component to be demonstrated instead of to the organ or tissue. The former change is in keeping with our better understanding of technology, and the latter change makes reference easier. "Carleton" has always been a reliable guide to practical and useful methods, and this present edition should prove as reliable as its predecessors.

Although nominally devoted to histology the text includes methods for enzyme histochemistry, exfoliative cytology, autoradiography, and for the demonstration of bacteria, fungi, protozoa, and worms. There are innumerable practical tips that will assist

the less experienced. A welcome innovation is a list of references with each chapter.

The illustrations have been usefully increased and the print is easier to read. The size of the page is a little larger and the number has increased from 318 to 400. I expect this edition to be even more useful than its predecessors, and I recommend it to anyone engaged in histopathology.

C. V. HARRISON.

Vaccines Against Viruses

First International Conference on Vaccines Against Viral and Rickettsial Diseases of Man. Pan American Health Organization Scientific Publication No. 147. (Pp. 695 + xxviii; illustrated, \$7.00.) Washington: Pan American Health Organization, 1967.

The programme of this congress was arranged under the headings of: the control of respiratory virus infections; exanthemata and mumps; smallpox, rabies, and hepatitis; enteroviruses; and rickettsiae and bedsoniae. One session was held on the problems of vaccination against these diseases. (See *Brit. med. J.*, 1966, 2, 1590.)

The information given in its long report is valuable to all those who practise control of infectious diseases, but the journalness of scientific communications makes many of the papers irksome reading. The value of the commentaries which follow each topic is greatly reduced by "discussants" not discussing, only adding more information, sometimes whole papers, to the load which the reader has already borne. However, the report does reveal new demands and policies which will affect immunization in the future.

Readers will know, or discover, that protection against killing and crippling diseases is not enough, and that immunization against minor infections is now under review. This

congress seems to favour a policy of no action against enteroviruses—poliovirus apart—but to view respiratory infections, though not common colds, in a more serious manner. Measles and rubella vaccines are considered at some length, and the papers make useful reading at a time when the virtual abolition of smallpox and poliomyelitis from certain countries has created environments in which only vaccines free of risk and of discomfort become acceptable.

Chemical treatment of viruses is being used in three ways—to fractionate pure virus antigens, so increasing relative effectiveness and lowering dosage; to disintegrate virions in the hope of broadening the specificity of antibodies induced; to conjugate haptens to antigenic proteins, so creating new antigens. The first of these methods is feasible, the last two controversial, especially in work with influenza and mycoplasma (which was included in the section on respiratory viruses).

The use of adjuvants, particularly a new oil emulsion, has strong advocates and some detractors. The discussion is useful here.

New phenomena continue to appear. It may be that the prophylaxis of virus infections of mucous membranes depends on the quality of antibody produced. There is a suggestion that protection against respiratory syncytial virus may fail because enough IgA antibody is not produced.

Tumour-forming viruses receive much attention, probably too much. Recent discoveries of "hybrid viruses" which have acquired tumour-forming capacity from contaminating viruses in tissue-culture systems will strengthen the desire of many to avoid all active virus vaccines. Certainly, if adenovirus vaccines are ever used, the use of chemically purified antigen, as suggested by one speaker, should obviate risks of injecting foreign nucleic acid during immunization.

These are all large fields to survey. The concluding speaker is right in saying that he would gladly have seen more time for discussion.

K. B. FRASER.

Books Received

Review is not precluded by notice here of books recently received.

Field Guide to Disease. A Handbook for World Travellers. By Berton Roueché. (Pp. 146, 21s.) London: Victor Gollancz, 1967.

Surgery for Acquired Mitral Valve Disease. By F. Henry Ellis, Jr., M.D., Ph.D.(Surgery), F.A.C.S. (Pp. 299 + xiv; illustrated, £5 19s.) London: W. B. Saunders, 1967.

Baby Gymnastics. By Detleff Neumann-Neurode. Revised by Wendula Kaiser. Photography by Hinde Baum. Translated from the German by Agnes Wenham. (Pp. 39 + xii; illustrated, 15s.) Oxford: Pergamon, 1967.

Cancer of the Breast. Major Problems in Clinical Surgery. Vol. 5. By John S. Spratt, Jr., M.D., and William L. Donegan, M.D. (Pp. 322 + xv; illustrated, £3 15s. 3d.) London: W. B. Saunders, 1967.

Symposium on Tumors of the Alimentary Tract in Africans. Held at Geneva, 1965. National Cancer Institute Monograph, 25. Edited by J. F. Murray. (Pp. 315 + xxiii, \$3.25.) Bethesda, Maryland: National Cancer Institute, 1967.

Gaseous Digestive Conditions. By Joseph H. Pollock, M.D., F.I.C.S. (Pp. 163 + xv; illustrated, \$7.00.) Springfield, Illinois: Charles C. Thomas, 1967.

Diagnosis and Treatment of Menstrual Disorders and Sterility. 5th edition. By S. Leon Israel, M.D. (Pp. 638 + xii; illustrated, £9.) New York: Harper & Row, 1967.

The Erotic Minorities. A Swedish View. By Lars Ullerstam, M.D. Introduction by Antony Grey. Translated by Anselm Hollo. (Pp. 146 + x, 30s.) London: Calder & Boyars, 1967.

Wirbelsäulen-Fibel. By Professor Hans Rettig and Dr. Kurt Kollmann. (Pp. 105 + vii; illustrated, DM. 16.80.) Stuttgart: Georg Thieme, 1967.

Peripheral Nerve Regeneration Using Nerve Grafts. By Leonard Marmor, M.D. (Pp. 107 + xi; \$6.75.) Springfield, Illinois: Charles C. Thomas, 1967.

Praxis der Selbsthypnose des Autogenen Trainings. By Dr. Klaus Thomas. (Pp. 90 + vii, DM. 9.80.) Stuttgart: Georg Thieme, 1967.

History Taking for Medical Students. By S. D. Bhandarkar, M.D., M.R.C.P., F.R.F.P.S. (Pp. 80, 3.50 rupees.) Bombay: Popular Prakashan, 1967.

Nutrition and Physical Activity. Symposia of the Swedish Nutrition Foundation, 5. Edited by Gunnar Blix, M.D. (Pp. 143; illustrated, 40 Swedish kroner.) Stockholm: Almqvist & Wiksell, 1967.

Speaking and Writing in Medicine. The Art of Communication. By Clifford F. Hawkins, M.D.Lond., F.R.C.P. (Pp. 159 + xviii; illustrated, \$8.50.) Springfield, Illinois: Charles C. Thomas, 1967.

The Haemolytic Anaemias. Congenital and Acquired. Part 4. 2nd edition. By J. V. Dacie, M.D., Hon.M.D.(Uppsala), F.R.C.P., F.R.S. (Pp. 993-1352 + vii; illustrated, 65s.) London: J. & A. Churchill, 1967.

Symposium on Tetanus in Great Britain. Held at Leeds on 7-8 April 1967. Edited by M. Ellis, F.R.C.S. (144 cyclostyled pages. Available on request for token payment.) Leeds: The Tetanus Unit of the General Infirmary, 1967.

New Concepts in Pain and its Clinical Management. Edited by E. Leong Way, Ph.D. (Pp. 224 + xiv; illustrated, 64s.) Oxford: Blackwell, 1967.

Infant Nutrition. By Samuel J. Fomon, M.D. (Pp. 299 + x, £3 13s. 6d.) London: W. B. Saunders, 1967.

Middle Articles

MEDICAL HISTORY

“Guérir quelquefois, Soulager souvent, Consoler toujours”

L. M. PAYNE*

Brit. med. J., 1967, 4, 47-48

The number of people who have sought for the origin of this quotation must be legion and those who have guessed at its source no less. These words have been used to summarize the vocation of both doctor and nurse. They have been attributed to people as widely separated in time as Hippocrates and Florence Nightingale, Paré and Edward Livingston Trudeau. In a recent paper¹ they were attributed to Oliver Wendell Holmes. The author had taken it from the *Practice of Dynamic Psychiatry* by J. H. Masserman, p. 359 (Philadelphia, 1955). It is significant that of all the quotations found at the beginning of each chapter this one alone lacked the precise reference, the author's name only being given. The fact that these words are found in Latin, French, and English does not make it any easier to document their earliest use. They are found in a window in the New York Academy of Medicine. They are part of the nurses' window in Guildford Cathedral. In a stained-glass window on the history of medicine in the Mayo Clinic they form part of the Lister window, in the description of which the saying is attributed to Trudeau.²

This may be because W. B. James, at a memorial meeting

* Librarian, Royal College of Physicians of London.

FIG. 1.—Bronze statue of Dr. E. L. Trudeau by Gutson Borghum. Formerly at Trudeau Sanatorium grounds, now at Trudeau Institute grounds on Lower Saranac Lake, New York. By courtesy of the Trudeau Institute.

to Dr. E. L. Trudeau in January 1916, told how he had first heard from him a quotation which, they used to agree, briefly and comprehensively described the ideal aim of a physician—“Guérir quelquefois, soulager souvent, consoler toujours”³; or it may be because at Saranac Lake these words are found on the memorial statue of Trudeau in the grounds of the Trudeau Institute (Fig. 1) and beneath an oil painting in the library (Fig. 2).

Since the dedication of the statue in August 1918, if not before, the librarian of the local public library, in common with many other librarians the world over, has sought in vain, far and wide, for the origin of this quotation.

FIG. 2.—Picture of Dr. E. L. Trudeau in library of Trudeau Institute at Saranac Lake, New York. By courtesy of the Trudeau Institute.

When Sir Theodore Fox in his Harveian Oration⁴ used this quotation as "the classical summary of the doctor's vocation" he avoided attributing it to any author. A. L. Donaldson⁵ said that Dr. Trudeau exemplified to the full the maxim of a great French physician which he was very fond of quoting. This may refer to Armand Trousseau; but a search of his works by one librarian⁶ has produced nothing nearer than "... une infirmité sans gravité, qu'on ne peut guère espérer guérir, mais qu'on peut toujours soulager" (*Clinique médicale de l'Hôtel de Dieu de Paris*, 2nd ed., vol. 3, p. 781, Paris, 1865). A similar saying is found in Paré⁷ in *Canons et règles chirurgicales de l'auteur*: "L'office du bon médecin est de guérir la maladie que s'il ne vient à cette fin, au moins faut-il qu'il la pallie." Witkowski, either alone or in co-operation with Cabanès, has written a number of works comprising medical anecdotes and quotations. In one of these he reproduces words attributed to Asclepiades⁸: "the duty of a physician is to cure diseases safely, quickly and happily." It was not until 1909 that Witkowski and Cabanès published a book⁹ with a chapter headed "Proverbes et dictons sur les médecins" which had original quotations in italic and comments in roman type. Beneath the quotation "La présence d'un Médecin profite beaucoup," which is preceded by the words "Au XV^e siècle, on disait," there is this sentence in roman: "Son rôle est de guérir quelquefois, soulager souvent, et consoler toujours."

In the light of this it may or may not be naive to suggest that in this form the quotation is no older than 1909, or the date when Witkowski and Cabanès collected the material for their book; it is clear, however, that a misreading of this book would account for the quotation being regarded as fifteenth

century or earlier. Perhaps it is one of those sayings which have, so to speak, evolved with the passage of time. Professor Ackerknecht,¹⁰ who provided the reference to Paré, thinks it is proverbial. In the Latin and English versions of Paré's *Canons* there has been some rearrangement as compared with the original French, with the result that there are two now fairly close together which embody the sentiments of cure, relief, and comfort:

6. It is the part of a good Physition to heale the disease, or certainly to bring it to a better passe, as nature shall give leave.

10. You shall comfort the Patient with hope of recoverie, even when as there is danger of death.¹¹

By recording known published references earlier than Witkowski⁹ some light may be thrown on its origin, even if the actual source cannot be found.

NEW APPLIANCES

Cardiff Laryngoscope for Infants

Dr. O. P. GRAY and Dr. M. ROSEN, Cardiff Royal Infirmary, write: The unreliability of laryngoscopes at present available is well known. The electric contacts, both between the folding blade and the handle and with the bulb, become worn in time and the light fails at a critical moment. In addition, the cost makes the widespread provision of extra instruments for occasional or standby use expensive.

The Cardiff infant laryngoscope overcomes these obstacles. It is a more reliable instru-

ment, and its low cost may make it financially possible to have infant laryngoscopes more readily available.

The instrument consists of a standard pen-torch adapted to receive a screw-fitting laryngoscope blade (Figs. 1 and 2). The blade shape is based upon that of the Seward infant laryngoscope, and is made of Perspex, polished except at the tip. The light transmission is excellent and provides a clear view of the larynx. A pen-torch was chosen since it is cheap and is possibly used by clinicians.

It seemed probable that a light used often for other purposes would be in good order when required as an emergency laryngoscope. The blade can be sterilized by immersion in aqueous antiseptic solution.

The laryngoscope is not only satisfactory in use, but is also of value for inspecting the pharynx of neonates, a difficult task without a laryngoscope.

We wish to acknowledge the assistance of Mr. J. Thomas, lately instrument maker at the United Cardiff Hospitals, for making prototype blades. We thank our numerous colleagues for trying the instrument, and the Department of Medical Illustration, United Cardiff Hospitals. We would also like to thank Vickers Medical (Oxygenaire Ltd.), from whom the laryngoscope is available, for their helpful co-operation.

Advantages of Health Centres

SIR,—From our 15 years' experience in the William Budd Health Centre we should like to make some comments on Dr. C. H. Warrick's article comparing practice in a health centre with group practice (9 September, p. 672). In Bristol it has been found that a pattern has evolved which might well be regarded as a basis for future development throughout the country. The provision by the local authority of nursing and secretarial staff has enabled general practitioners not only to use their time to the greatest advantage to run their own antenatal and infant welfare clinics in the closest possible co-operation with the obstetricians and local authority, but also to perform a variety of screening procedures, clinical investigations, and minor surgical procedures which normally occupy much of the time and resources of casualty and other departments of hospitals, and for which the "cottage industry" doctor has neither the facilities nor assistance.

Some people have suggested that "casualty units," complete with x-ray equipment, etc., should be set up in health centres and staffed by general practitioners on a sessional basis. This would undoubtedly ease the work load on the undermanned hospitals, and, by a simple extension of this idea, health centres could become local diagnostic units at which consultants could hold their "outpatients" sessions, thus saving further pressure on the hospitals and much waiting and travelling time for patients. Arrangements such as these would also serve to bring about a mutual understanding of their various problems by the consultants and general practitioners, as well as eliminating patients' fears, which seem to be engendered by the hospital environment. Furthermore, the newly qualified doctor, when entering general practice, would not find himself suddenly deprived of the scientific and paramedical assistance to which, as a student and houseman, he has become accustomed, and would not feel that he was entering a cottage industry and an inferior part of medicine. Special skills acquired in hospital could be usefully employed and would not undergo disuse atrophy. A feeling of satisfaction could replace frustration, and the service given to patients could be improved.

It may be said that any group of general practitioners can get together to provide their own purpose-built centre, and this is obviously true. The trouble is that with the present-day high price of land and building the initial financial burden on the doctors would be prohibitive, and with high maintenance costs there is no doubt that doctors embarking on such a scheme under the present system of payment would be subsidizing the Government health services out of their own income. Although the obstacles might be formidable, even privately owned health centres might be possible to maintain if general practitioners were paid on an item-of-service basis for

all the additional services provided. In privately owned health centres it would often be difficult to obtain the same high degree of co-operation between general practitioners and local authority services—a co-operation which has proved valuable to both parties and the patient as well. While it is often thought that doctors working in health centres derive some benefit for themselves, it cannot be too much emphasized that the real benefits are bestowed on the patient, in so far as the doctors, relieved of work which can be quite properly delegated to ancillary workers, are able to devote more of their time and energy to providing a better service to the community. This was in very large measure the object of the planning of this health centre, and we are confident that this has been achieved. There can be little doubt that the quality of service provided is the yardstick by which the value of health centres should be judged. It is believed that economy of costs can be effected if general practitioners and local authority utilize the same premises. The great advantage of privately owned health centres is of course that the security of tenure is absolute, and this factor poses one of the greatest problems faced in regard to those provided by local authorities.

The time has now come when there should be a conference of general practitioners who actually work in health centres to pool their views and iron out problems. The practical doctor must have many ideas for future development, and these should be communicated to the Ministry and the profession. For too long have we been advised by the armchair theorists who have no working knowledge of health centres, but who spend their time telling other people how to do good general practice; and it is these same armchair theorists who seem to have the ear of the Ministry and the profession at the present time.

At the cross-roads at which the National Health Service now stands, any means which can be found to ease the increasing burden of the general practitioner and at the same time give him a real sense of fulfilment in following his vocation should be grasped, and it would seem that the provision of health centres falls into this category.—We are, etc.,

EDWARD LACE.

Melanoma, Halothane, and Liver Necrosis

SIR,—While the similarity may be coincidental, the following two deaths have common features that seem to be worth recording.

Miss A., aged 39, had a melanoma removed from her leg under local anaesthesia. As histological examination showed malignancy with lymphatic invasion, the femoral artery was can-

nulated for infusion of the cytotoxic agent S.P.I. (podophyllic acid hydrazide). On the fourth day the cannula became displaced and was reinserted. On the eighteenth day the scar was widely excised and a skin graft applied. These three procedures were carried out under general anaesthesia with thiopentone, nitrous oxide, and halothane. On the twenty-first day she was drowsy, disorientated, and jaundiced. She died on the twenty-third day. Necropsy showed necrosis of the liver. There was no recurrence of the melanoma.

Mr. B, aged 75, had a melanoma of the back. He had an unexplained thrombocytopenia but no other abnormality. The melanoma was removed, and, as it was found to be malignant, 11 days later it was widely excised and a skin graft applied. He received two pints of fresh and two of stored blood. On the fourteenth day the dressing was changed. The three procedures were carried out under thiopentone, nitrous oxide, and halothane. On the fifteenth day he became jaundiced and he died on the seventeenth day. Acute hepatic necrosis was found. There was no recurrence of the melanoma.

Halothane was theoretically considered as a possible cause of liver damage, but the incidence of jaundice after its use is no higher than that in the general population.¹ There is, however, said to be an increased incidence of hepatic necrosis in patients who have been repeatedly anaesthetized, and halothane sensitization has been postulated.² S.P.I. is not thought to be specially hepatotoxic. It has never been suggested that melanomata produce any internal toxins. Whether the thrombocytopenia in the case of Mr. B was significant was not decided. The connexion between these two deaths remains purely speculative.

The patients were under the care of Mr. W. H. W. Jayne and Mr. G. Westbury.

Prescribing and Withholding Psychotropic Drugs

SIR,—Should we not give more consideration to the criteria for withholding the so-called psychotropic drugs?

Major psychiatric and psychological derangements warrant risks commensurate with their severity, but it is for minor neurosis that the bulk of these drugs is consumed. It is becoming disturbingly common for patients, not past middle life, to regard their medication as a permanent regimen and to attend for prescriptions with a regularity suggestive of dependence.

It is difficult to assess the long-term effects of tranquillizers and antidepressants on the course of the various neuroses, while the safety of permanent regimens of a wide multi-

plicity of new drugs can hardly be taken for granted. Should there be any parallel with the effects of alcohol, for example, in a few years' time there could be a crop of iatrogenic delirium tremens and liver cirrhosis which would hardly bear contemplation.

We should not forget that the present stupendous amphetamine consumption, legitimate and otherwise, was initiated by ourselves, just as the overconsumption of barbiturates is a legacy of the sedative era.

Past experience gives a clear warning. Our collective therapeutic machine is very sensitive to the accelerator and we are driving without brakes.—I am, etc.,

Sheffield.

Treatment of Poisoning by Antidepressants

SIR,—Recent progress in elucidating the metabolism of imipramine and amitriptyline lends strong support to the plan of treatment proposed by Dr. C. M. Steel and others (9 September, p. 663). The important points are:

(a) These drugs and their metabolites are very rapidly excreted, predominantly in the urine. Christiansen *et al.*¹ gave radioactive imipramine to 21 patients and found an average of 40% of the radioactivity in the ensuing 24-hour urine. In our laboratory here we have confirmed and extended this.

(b) Imipramine circulates in the blood, about 90% bound to plasma proteins and therefore undialysable.²

(c) The binding of the drugs to protein, whether in blood or tissues, is not firm, as Dr. Steel and his colleagues state, but labile and reversible.³

(d) Destructive metabolism, principally hydroxylation and glucuronide formation, is rapid and takes place in the liver.⁴

(e) Bile contains a good deal of drug metabolites, which pass into the intestine and are then largely reabsorbed into the circulation.⁵

The protein-binding of the drugs helps to explain why peritoneal and extracorporeal dialysis are ineffective treatment for an overdose. The rapid metabolism of the drugs explains why methods which measure only the drugs themselves and not their various metabolites fail to account for much of the overdose in the urine. (The heptane method mentioned by Dr. Steel and his colleagues does not extract the metabolites.) Other methods, however, will demonstrate rapid excretion. This explains why, provided blood pressure remains adequate for kidney function, the overdose can be rapidly cleared from the body without any special intervention. The literature in fact contains quite a number of reports of severe poisoning, with coma and convulsions, in which with prompt control of the fits patients recovered smoothly in two days or so and were none the worse for the experience (as in Dr. Steel's Case 31). This is what one would expect with a high excretion rate, and makes the tricyclic antidepressant drugs safer than their alarming symptoms would suggest. Circulatory collapse is the great danger, but seems uncommon in these cases. Perhaps, then, it might still be possible to draw off the drug and its metabolites through the bile (duodenal intubation?).

Dr. Steel and his colleagues do not discuss prevention of poisoning with these drugs. There are two relevant points here. They do not mention the sex of their child cases,

but in the literature the vast majority were boys, particularly from 18 months to 5 years old. This, then, is the population at risk. The majority of people bringing the drugs into the home are depressed women, in some cases mothers of boys. Now people with depressive illnesses are apt while ill to be forgetful, careless, and even fatalistically ready to run unnecessary risks—all as part of their sickness, and different from their normal personalities in health. This suggests, therefore, that when we prescribe tricyclic antidepressant drugs for treatment at home we should always inquire whether there are young children, especially boys, in the house and arrange that the tablets are in the care of a responsible relative (for example, husband) for daily issue, rather than in the care of the patient herself.—I am, etc.,

SIR,—In the article by Dr. C. M. Steel and others (9 September, p. 663) the authors recommend using paraldehyde instead of barbiturates in the treatment of convulsions caused by overdose of antidepressive drugs such as amitriptyline.

However, paraldehyde is potentiated by other central nervous system depressants (and vice versa); and in large doses, which may be necessary to control fits, is known to depress respiration and circulation.¹ Also paraldehyde has been proved to reduce the contractions of mammalian heart-lung preparations.²

In their article the patient cited had a low minute volume before paraldehyde administration, but no second reading was given afterwards, only the bland statement that no ventilation was considered necessary. As respiration and circulation are already depressed in overdose with antidepressives, I consider that neither barbiturates nor paraldehyde should be used, but that tubocurarine or a related drug should be given for convulsions and the patient's ventilation controlled. This would not prove awkward, as any unit treating such cases should have facilities to use artificial ventilation; and the harmful effects of antidepressive drugs have disappeared by 24–36 hours following ingestion; provided no other depressive drugs are administered.—I am, etc.,

SIR,—I was interested to read the excellent report on treatment of imipramine and amitriptyline poisoning by Dr. C. M. Steel and others (9 September, p. 663) and would like to make the following comments.

The writers rightly stress the possibility that any factor increasing the cardiac work load in these cases may precipitate the cardio-toxic effects of the drugs,¹ and it is clearly important, therefore, to prevent convulsions. However, the use of the enforced diuresis method of treatment in poisoning is unlikely to increase significantly this risk when infusing fluid into a young, healthy subject with normal renal function and at a rate commensurate with the diuresis. In the situation previously described² there was a progressive fall in the amount of metabolites excreted in the urine during diuresis, which was paralleled by the clinical improvement. It is true that the renal excretion of the free drug is low, but, as pointed out by Dr. Steel and his colleagues, we do not know the pharmacological activity of all the metabolites excreted in the urine; they may be responsible for some of the effects of poisoning by this group of drugs.

It would seem unwise in our present state of ignorance to deny the patient any treatment that may increase renal excretion of the drug or its metabolites, especially as the patient may be continuing to absorb the drug present in the gastrointestinal tract beyond reach of the gastric lavage, and whose blood stream may contain amounts of the drug or its metabolites as yet unbound to the tissues. Likewise, it may also be unwise to imply that peritoneal or extracorporeal dialysis is of no use in such cases of poisoning because of previously reported failures,³ for these cases may have been irreversibly affected by the cerebral and cardiovascular effects of the drug before dialysis was started.—I am, etc.,

Kwashiorkor in Children

SIR,—The detailed haematological survey of children with kwashiorkor by Professor E. B. Adams and his colleagues (19 August, p. 451) is of considerable value, particularly as there are no complications such as malaria and hookworms in Durban. Recent experience in Kampala is pertinent to two points which they raise: firstly the aetiology of the anaemia, and secondly the need for blood transfusion.

One hundred and twenty-two children with kwashiorkor have been admitted since January 1966; 35% had hookworm infestation, 22% malaria, and 13% sickled (three children were homozygous SS on haemoglobin electrophoresis).

Fifty-three of the 122 children had none of these complications. In 25 of these the haemoglobin level was less than 10 g./100 ml. and this "anaemic" group has been compared with the other 28 "non-anaemic" group. Both groups had a mortality of 10%, and similar sex distribution and anthropometric measurements. Clinical signs were also similar, except that the "anaemic" group tended to have more florid hair changes, although the subjective nature of

this sign makes assessment difficult. There was, however, a distinct difference between the mean concentrations of plasma protein in the two groups. Fourteen (55%) of the "anaemic" children had plasma protein levels of below 4 g./100 ml., whereas only 5 (18%) of the "not anaemic" ones had such low levels ($P < 0.01$). This provides some circumstantial support for the association between protein deficiency and anaemia found in Durban.

Blood transfusion for children whose haemoglobin level is less than 6 g./100 ml. is recommended by Adams *et al.*, and this was also the policy here at one time.¹ It is high compared with the 4 g./100 ml. recommended in Jamaica,² and since the introduction here of a low sodium diet providing 1 mEq/kg./day of sodium instead of the 6 mEq/kg./day formerly used it has been possible to manage successfully children with haemoglobin levels of less than 3 g./100 ml. without transfusion.³ The mean change in haemoglobin at the end of the first week in 29 children receiving a low sodium diet was -0.15 g./100 ml., compared with -0.95 g./100 ml. in 30 children on a high sodium diet ($P < 0.001$). It would be of value to know the sodium intake of the Durban children. There seems some virtue in avoiding a transfusion whenever possible in these children, not only because of the cost and possibility of reactions, but also because of the reduction in cardiac output and inulin clearance following intravenous plasma in malnourished children.⁴

Since the introduction of the low sodium diet a rapidly falling haemoglobin has now become very suggestive of an infection, particularly a Gram-negative bacteraemia. We have no rule of thumb for blood transfusion now, but a rapidly falling haemoglobin in the presence of a proved or suspected septicaemia seems a reasonable indication in Kampala, although not necessarily elsewhere. In our experience the "Dean" diet⁵ has continued to give satisfactory results in most children, although, for the reasons just given, we now recommend a reduction in the percentage of sodium.³⁻⁶

To summarize, therefore, our experience in Kampala suggests there is an "anaemia of protein deficiency," but that the use of a low sodium diet enables children with kwashiorkor to be treated without blood transfusions unless there is a complicating septicaemia.—I am, etc.,

Carcinogenic Properties of Ortho-dianisidine

SIR,—Further to Dr. H. Lehmann's letter (19 August, p. 494) I should like to use

your columns to ask the manufacturers of the widely used reagent tablets "Occultest" and "Hematest" (the Ames Company) whether the tablets contain ortho-tolidine or a related compound, and in what quantity? If one or more of these substances is present in these tablets, do they intend to state this on the label in future?—I am, etc.,

E. D. ACHESON.

Nephrotic Syndrome in Patient Taking the "Pill"

SIR,—The contraceptive pill has been incriminated as the cause of a variety of conditions. So far, a possible nephrotoxic property has not been demonstrated. Recorded here is a case where a nephropathy occurred during the use of oral contraception.

A 23-year-old nulliparous woman developed extensive oedema of the lower limbs eight days after commencing Ortho-Novin (norethisterone, 2 mg. and mestranol 0.1 mg.). The oedema persisted during three months of pill-taking, and she was found to have gross proteinuria with resultant hypoproteinaemia. The serum cholesterol was elevated and there was an increase in plasma alpha-two globulins and absent gamma-globulin. She had therefore developed the nephrotic syndrome and this has persisted for three months since the withdrawal of the contraceptive pills.

Excretion pycelography displayed a right hydronephrosis for which no cause was apparent. There was no evidence of renal vein thrombosis or other cause for the nephrotic syndrome. Apart from one attack of cystitis a year previously, there had been no renal symptoms prior to this present episode, and the patient had been in excellent health.

Does this case demonstrate a nephrotoxic property of the "pill"—or was it a coincidence that the nephrotic syndrome occurred so quickly during the use of oral contraception?—I am, etc.,

North Devon Infirmary, ALAN J. RILEY.
Barnstaple.

Aversion Therapy in Management of Homosexuals

SIR,—May we reply to the comments made on our paper (3 June, p. 594) by Drs. I. Bieber (5 August, p. 372) and B. Kalcev (12 August, p. 436)? Dr. Bieber takes issue with our claim for a near 60% success rate, considering that only 13 of our cases (30%) shifted to exclusive heterosexual behaviour, another seven cases (16%) becoming heterosexual though not exclusively so. He compares these percentages with his own figures—27% became exclusively heterosexual and an additional 15% became "actively heterosexual though not exclusively so."¹

Our Table VII states clearly: (1) 20 patients (46%) displayed no homosexual practice or fantasy post-treatment, while another five (12%) used weak (i.e., occasional) homosexual fantasy. (2) 13 patients were actively practising heterosexual intercourse (the 13 accepted by Bieber as being exclusively heterosexual), seven were also displaying heterosexual behaviour, though as yet

falling short of sexual intercourse—a not unusual phenomenon—and another five were either "dating" females or using strong heterosexual fantasy. All these data are summarized in our Table VIII in which 23 patients received a post-treatment Kinsey rating of 0 or 1 and two patients a Kinsey rating of 2. That is, none of the 25 patients described as improved were displaying homosexual practices, although six of them still showed occasional interest in directly observed males, and another five used occasional and weak homosexual fantasy. Twenty of the 25 were displaying overt heterosexual behaviour. Where overt sexual behaviour was displayed it was heterosexual in every case; where it was not the weight of interest and fantasy was much towards the heterosexual side of the continuum. The confusion arises because Dr. Bieber uses sexual intercourse as the synonym for sexual behaviour and interest. His 16 cases (see above) who were displaying "heterosexual behaviour though not exclusively so" were therefore bisexual—that is, practising both heterosexual and homosexual intercourse. Overt behaviour is not the only indicator of sexual orientation. It seems sensible to use, in addition, fantasy and desired behaviour, particularly in the absence of overt behaviour. As we pointed out in our paper, the five patients who were having sexual intercourse with their wives prior to treatment had to use homosexual fantasy in order to do so. If we look at sexual behaviour as a balance between heterosexual and homosexual components it seems reasonable to state that nearly 60% of our series were towards the heterosexual end of the continuum post-treatment.

Even if the outcome of treatment was similar in the two series aversion therapy would be the treatment of choice. Our patients received an average of 18 to 20 sessions, each lasting 20 to 25 minutes. Of Dr. Bieber's patients 78 (75%) had 150 sessions (hours) of treatment or more, and of these 38 (36%) had 350 sessions or more. With two exceptions improvement was confined to those receiving 150 sessions or more.

Of the 24 cases in our series who had been practising homosexuality for 10 years or more six became Kinsey 0 after treatment and four Kinsey 1. None of these 10 cases displayed overt homosexual behaviour post-treatment, six of them were having heterosexual intercourse, and two displayed overt heterosexual behaviour short of intercourse.

The term abnormal psychogenic development was used by Schneider² to describe personality aberrations which were not dependent on the patient's sexual status and which when present indicated a severely damaged personality, usually of the self-insecure or attention-seeking types. Non-psychoanalytic workers such as ourselves cannot hope to explore our patients' personalities in very great detail, although we are aware that it is possible to detect abnormal psychogenic developments in relation to relatively insignificant events. We must concede that the personality classification is crude. However, it has the merits of working at a clinical level, and of being used by the World Health Organization.

In reply to Dr. Kalcev, 10 out of the 18 of our series of cases who presented in connexion with a court appearance showed an improvement after treatment. Hence, referral by court is not necessarily a contraindication for success. However, irrespective of success we agree that there is indeed a moral issue here. It is certainly wrong to impose treatment on anyone, and a choice of being sent to prison or receiving treatment is hardly an adequate test of free will.

The term personality disorder is used to describe a serious problem of personal function-

ing other than homosexuality. A high proportion of those who presented for treatment displayed personality disorders because such individuals are more likely to seek help from psychiatrists than those with more normal personalities, particularly as homosexuality has been widely thought of as being beyond help. Dr. Kalcev excludes the seven cases who were sexually attracted to those under the age of 16 from the group which he describes as "subject to a treatment because of society," yet paederasty is the most heavily punished offence.

The argument that it is society that is wrong is very misguided. Which seems more unethical: to treat someone in distress, or to suggest to him that he waits until his practice is as socially acceptable as heterosexuality? The vast majority of our patients have been sad and unhappy individuals seeking help for a problem they see as central in their lives, and pleased with the results when these have been successful. When asked for their motives for wanting to change most patients stated a desire to marry and have a family; surely a long way from 1984, unless we consider such motives as evidence of a dark conspiracy towards social conformity.

Finally, may we make a plea for a less pejorative approach to discussion in this field? We consider our own research efforts as little more than a first approximation, and the problems remaining as greater than those so far attempted—for instance, the relative aetiological importance of genetic, intra-uterine, and early experience factors, the investigation of heterosexual behaviour as a form of social skill, and the importance of single-trial learning at critical periods in establishing and perpetuating specific forms of sexual behaviour.—We are, etc.,

M. J. MACCULLOCH.

Screening by Cervical Cytology

SIR,—The known facts on the incidence of cancer of the cervix prove the Ministry to be wrong in refusing the screening service to women below the age of 35 years.

My records for 200 consecutive cases of carcinoma-in-situ of the cervix and 200 of invasive carcinoma of the cervix show an age incidence as follows:

	20-29	30-39	40-49	50-59	60-69	70-79	80-89	Average
Cervix in situ ..	29	70	67	26	6	2	0	39
Cervix invasive	3	25	45	70	38	16	3	54

During the year 1966 our screening service found 144 women with positive smears. Their ages and the source of the smears are:

	16-20	21-25	26-30	31-35	36-40	41-45	46-50	51-55	56-60	61-65	66-70	71-75	76-80	81-85	Total
Local authority clinics ..	2	3	3	8	19	15	3	4	—	—	—	—	—	—	57
Hospital cases ..	3	6	2	7	5	9	4	6	6	5	2	1	2	1	59
Antenatal clinic and postnatal clinic..	1	2	4	1	—	1	—	—	—	—	—	—	—	—	9
General practitioner	3	—	3	1	7	2	3	—	—	—	—	—	—	—	19
															144

The highest-risk type for cancer of the cervix is the woman who marries early, usually has many children, and is house-bound because of her many cares and low social status. Any national screening programme which leaves out, almost entirely, the highest-risk cases is sure to prove a costly disappointment, worse than this it is likely to lead to quite false conclusions. The Ministry should not only pay general practitioners for taking smears regardless of age but also encourage this before the age of 35 rather than after it. The highest risk cases can be reached only by those who attend them in their many pregnancies and by the home nurses on the staff of the medical officer of health.¹ Dr. Leyshon has found that by the time a woman dies with cancer of the cervix she uses up nine months of a home nurse's time. This home nurse is available for the screening service only when not required for sick cases. Medical officers of health should have a number of home nurses for this work only.—I am, etc.,

Drugs and Driving

SIR,—I fully appreciate the layman's dilemma expressed by Mr. John Allan (16 September, p. 739). Nevertheless, Dr. D. V. Foster's remark about "rapport existing between doctor and patient" (24 June, p. 836), endorsed by myself (8 July, p. 109), was not intended to be considered out of its original context, but by so doing Mr. Allan has not surprisingly slanted the emphasis.

At present it would appear that very little is known about the possible effects of the powerful psychotropic and psychosedative drugs we are prescribing on our patients' driving performance. A recent pilot survey on my own psychiatric outpatients showed that approximately one in five are regular drivers while receiving psychiatric drugs singly or in combination. When viewed nationally this represents a not inconsiderable proportion of motorists. The majority believed that their reactions were not impaired and were sometimes even improved by medication, but this situation is merely comparable to the subjective effects produced by alcohol on the mildly intoxicated driver. A number of learner-drivers have come to my notice who take quite large doses of tranquilizers before undergoing driving tests, which would appear to be a surprisingly dangerous practice. The problem is, however, not peculiar to motorists. Some years ago the driver of an express plying between Shrewsbury and Paddington was receiving chlorthalidose

(Librium) 90 mg. daily to reduce anxiety, fortunately without untoward incident, but had an accident occurred one can imagine the Court's reaction to the divulgence of this information.

Applicants for motor-vehicle licences must now disclose whether they "suffer from any form of mental disease or defect," and if so give particulars. This might be taken to include reference to drug treatment, although such information is not specifically requested. Insurance companies do not yet seem to be alive to the problems of drugs and driving, as evidenced by their proposal application forms, despite the fact that the drug alcohol is recognized as a major cause of road accidents. If we are to attempt to halt the increase in accidents then perhaps stiffer medical examinations should be instituted before an individual is permitted to drive a vehicle.

As doctors we must know the effects of the drugs we prescribe on our patients' ability to drive. Only then will we be in a position to offer sound advice.—I am, etc.,

Shelton Hospital,
Shrewsbury, Shropshire.

J. C. BARKER.

Taking Blood Samples

SIR,—A programme was shown on B.B.C. Television ("Twenty-four Hours," 19 September) featuring experiments on the lines of the new breathalyser tests, in which a volunteer was shown about to have a blood sample taken from the tip of the right thumb.

Excluding possibly the eye, I can think of no area where accidental infection of a needle puncture wound could produce such grave and permanent disability as in the pulp space of a digit, especially that of the thumb of the dominant hand. In addition, the highly sensitive skin of the finger tips makes the site inappropriate.

I hope we can rest assured that no member of the public will be asked to agree to blood sampling by this technique for police tests.—I am, etc.,

Cumberland Hospital, W. JOAN FERRABY.
Mitcham, Surrey.

Doctors for Industry

SIR,—Having read the leading article "Doctors for Industry" (16 September, p. 692), I cannot let this pass without comment, and hope that you will find space to publish my letter.

Firstly, I would point out that I represented the Association of Certifying Factory Surgeons on the subcommittee of the Industrial Health Advisory Committee of the Ministry of Labour, and as such find it difficult to comment on a document to which I am a party.

Secondly, I would say that in the main we support the Ministry of Labour report¹ but do not necessarily agree with all the recommendations therein. We are not happy with the format of the suggested certificate. Nor are we happy with the idea that the certificate should be handed to the employer, for this would undoubtedly lead to discrimination.

As regards the suggestion that there should be 100 full-time "A" doctors, my feeling is that there has been misunderstanding here. At the outset it was indicated that if full-time doctors were to run the new service this could be done by between 80 and 100 doctors, but I am not of the view that it was ever intended that the new service should be run by full-time doctors, but by part-time, as at present, and that the number required would be about 400 instead of the present 1,600 to 2,000. It is a known fact that at present 80% of all appointed factory doctors' work is carried out by 20% of the appointed factory doctors—namely, about 400.

Far from accepting our demise with equanimity, we view the new service as a challenge, and a worth-while job for us to carry out with skill and experience.—I am, etc.,

G. A. LAWRENSON,
Honorary Secretary,
Association of Certifying Factory Surgeons,
Manchester.

REFERENCE

¹ *The Appointed Factory Doctor Service*, Report by a Subcommittee of the Industrial Health Advisory Committee, 1966. H.M.S.O.

SIR,—Care of young people except in cases of gross disability is apparently to be abandoned by the factory medical inspectorate. Apparently the *B.M.J.* concurs (16 September, p. 692), and we may soon expect to see the School Medical Service thumbing their textbooks to adjudicate on flaws before fixing red labels for types of defect. What I find disturbing is specious support for official views on a narrow department line. The wider issues and inconvenient aspects which conflict with official policy are ignored.

What are the problems of young people leaving school for work in the metamorphosis of adolescence? What is the meaning of medical care in terms of "whole-man" medicine and particular adolescent stresses? What is the aim of health and educational services in regard to young people? In what way should services be co-ordinated? What information do we need? Is the Ministry of Labour the right place for the care of young people to be centred? Is there need for a service to be developed, rather than to be abandoned, by the A.F.D. as a member of a team, particularly with a reorganized Youth Employment Service and the School Medical Service? Why has survey and experiment before legislation been barred?^{1,2} Is not better care of the less able and socially handicapped young person a field of major economic and social importance? Is it a field where a red card system for the grossly handicapped and virtual abandonment of the rest is medically or socially or educationally acceptable?

There are many other points—and opportunities—to be considered, and it is sad to see your journal preoccupied with physical aspects of health at a time when so much new thinking is pointing the way to changes in the concept of medical care of the young.—I am, etc.,

M. E. M. HERFORD,
Appointed Factory Doctor,
Farnham Royal, Bucks
Windsor and Slough District.

Restrictions on Doctor in South Africa

SIR,—You have already published a letter from very distinguished members of the scientific and medical professions expressing the strongest disapproval of the banning in South Africa of Dr. Raymond Hoffenberg, a most distinguished worker in medical research (26 August, p. 556) and have supported their opinions with an excellent leading article (same issue, p. 512). The effect of the ban is to sterilize his future work. He is still young and it is impossible to estimate the loss to human knowledge and medical science.

We, his former associates at New End Hospital in Hampstead, wish to associate ourselves with these protests. In addition, we wish to point out that the Ministry of Health has now an excellent opportunity of reversing the scientific "brain drain" which has been causing so much anxiety. Dr. Hoffenberg, if he leaves South Africa, will never be allowed to return. Here in Britain he has no source of income. We suggest that a professorial or senior consultant post should be created for him at once. Such a move would be of the greatest advantage to medical research in Britain.—We are, etc.,

GEOFFREY KEYNES.

Emergency Admissions for the Elderly

SIR,—The following circular from our hospital group has been received.

"Geriatric Admissions"

"Elderly patients with an acute medical illness requiring admission to hospital are admitted to the geriatric wards at the Kingston Hospital and Hull Royal Infirmary parallel with the rota for acute medical admissions. When geriatric wards are full, and on admission days for Sutton, geriatric medical emergencies are admitted to acute medical wards, but this facility is liable to interfere with the true function of the acute medical wards unless all general practitioners co-operate in restricting as far as possible the number of elderly patients admitted in this way.

"Long-term illness and social problems in the elderly should be referred to the geriatric out-patients or geriatric physician where appropriate.

(Signed)"

What is the true function of acute medical wards but to treat acute medical emergencies? The implication of the above is surely that two standards of medicine are being employed and that elderly patients are regardlessly being shunted into a "chronic" ward.

All doctors experience difficulty over the elderly patients. Some people at 70 are spry and active mentally and physically, yet an acute illness would result in their admission to a chronic ward in the hospital; others at 60 are prematurely old and senile, yet presumably would be admitted into an acute medical ward by reason of their age. Why should an arbitrary decision be made to deny someone the benefit of modern treatment by reason of their age alone—surely *all* should be admitted to acute medical wards and only after initial treatment should they be trans-

ferred to wards for the chronic, the senile, the dying, and the hopeless cases.

General practitioners are now experiencing difficulty in getting elderly, but mentally and physically active, patients to return a second time to a geriatric ward. One experience has been enough, and the general practitioner is faced with the plea from the patient, "Don't send me back to *that* ward, doctor." Surely the general practitioner who has seen the patient at home is the one to decide whether the patient should be admitted in an emergency to a general ward or a geriatric one.

There is an impression that patients over 65 are going to get different treatment, which the hospitals will surely deny, but then why is it necessary to differentiate admissions by age?

Examples of doctors over 70 now active and fit can be quoted. Will they go to the chronic geriatric wards if they become acutely ill? Is no thought to be given to the mental state of an active elderly person in a bed between two senile dying "chronics"?

Long-term illnesses and social problems to, a special department—yes. But differentiate by age alone—*no*.

The hospitals could reply quite legitimately that there are times when they are asked to admit as acute medical emergencies patients who are not so.

This is the basis of the reluctance to admit patients over 65 to the acute wards—it is felt that a bed will be blocked by a patient for whom nothing can be done, and this may deprive a patient for whom something can be done of a bed. Could the answer be that the hospital authorities try trusting the general practitioner to give an honest assessment of the patient's need?

But the answer can never be the arbitrary refusal to admit an emergency into an acute medical ward on the grounds that the patient is over 65.

The public cannot be held blameless, for all too often they put pressure on the medical services to absolve them of the responsibility of looking after their own. The general practitioner must accept his share of responsibility for succumbing too easily to this pressure, but surely the solution, as put forward by the hospital, cannot be correct.—I am, etc.,

Hull.

D. F. C. DEACON.

Resuscitation of the Elderly

SIR,—The report on the B.B.C. television programme "Tomorrow's World" that the doctors at Neasden Hospital had instructions from their medical superintendent not to resuscitate patients over the age of 65 years makes it necessary to restate some of the basic tenets upon which modern care of the elderly is based.

The pessimistic, if not nihilistic, attitude towards therapy of the elderly in the past was based on the misconception that the elderly responded poorly to treatment and that even if they did respond they were in some way "chronic." Analysis of the terms "acute" and "chronic" and their more restricted usage would do much for the cause of modern practice of medicine in the elderly (and, more widely, the practice of geriatrics).

If one analyses the disease processes pre-

capitating direct admission of patients to general medical and geriatric assessment wards one finds that the majority of patients admitted to both types of ward are suffering from chronic diseases, but have been admitted for an acute episode occurring in the course of the disease. In the mediatic or general medical group of patients aged 15-60 or 65 years examples of common chronic diseases that necessitate admission because of an acute clinical episode are: diabetes mellitus (ketosis, infection), hypertension (left ventricular failure), atheroma of coronary arteries (cardiac infarction), chronic nephritis (renal failure), peptic ulcer (haematemesis). Similarly, the geriatric group of patients are also usually admitted for an acute episode occurring in the course of a chronic disease.

It is helpful to analyse further the tempo of disease at different ages to show that the indiscriminate use of the word "chronic" has given rise to the false concept that the elderly and their diseases are in every way slow or "chronic." Acute disease and acute episodes based on chronic disease arise equally abruptly in the elderly as in the middle-aged. The onset in the elderly, however, may be frequently less dramatic and more easily missed. The duration of the acute disease or acute episode in the elderly is usually comparable in length to that in the middle-aged. It is the recovery phase of the acute illness, however, that is often prolonged in the elderly compared with the middle-aged. The prolonged recovery phase of the elderly is often due to the disease being complicated by a physical or mental disability. It is important, therefore, to recognize that acute episodes in the elderly arise as abruptly and are as short-lived as at other ages. It is also important to be clear that the slow recovery phase does not mean that all phases are "chronic."

The difficulties of recognition of the acute episode combined with the slow recovery phase in the elderly have in the past helped to perpetuate the myth that age and chronicity go hand-in-hand. Many elderly people, however, suffer an acute episode from which they recover completely. At any age an acute episode such as ventricular arrest may occur (often precipitated by an anatomically small area of cardiac infarction) and if rapidly rectified may lead to continuance of life of an unaltered quality. There is no medical argument to support the exclusion of a group of patients, defined empirically on age alone, from standard methods of resuscitation.—I am, etc.,

St. Margaret's Hospital,
Nr. Swindon, Wilts.

BRIAN LODGE.

Neasden Memorandum

SIR,—I was delighted to read the letter from so many members of the staff of the Central Middlesex Hospital (30 September, p. 861) supporting "the undoubted integrity of Dr. McMath." Not only was it the B.M.A. who failed to point out the difficulties to the public, but so did the Minister of Health himself and the regional hospital board concerned.

It is true that there was some "small print" stuff commending Dr. McMath on his conscientious approach to this very difficult problem, but the overwhelming impression was that he was being condemned by the Minister and regional hospital board alike (30 September, p. 858).

It really has come to a sad pass when such a person as Dr. McMath can no longer rely on the support of his senior officers, who could so easily have smoothed the whole matter over with some simple explanations to the public instead of turning him into a scapegoat as your correspondents so rightly point out.—I am, etc.,

Hitchin, Herts.

O. H. E. BAYLES.

Remission in Acute Leukaemia

SIR,—We have read with interest your leading article on rubidomycin (3 June, p. 587). Much emphasis has been given recently to this new antitumour antibiotic isolated in France by Dubost *et al.*¹ and active mostly in acute leukaemia.

We should like to report our experience in acute childhood leukaemia using daunomycin, an antibiotic of the antracycline group, a substance identical with rubidomycin. Daunomycin was obtained independently by Di Marco *et al.*²⁻⁴ in the research laboratories of Farmitalia from cultures of *Streptomyces peucetius* sp. nova. The initial clinical trials were done at the National Cancer Institute in Milan⁵ in 1964 and at the Memorial and James Ewing Hospital⁶⁻⁷ from July 1964.

Our experience is summarized in the following Table:

Case No.	Disease	Courses	Disease Progressed	No Change	Remissions	
					Complete	Partial
1	Acute lymphoblastic leukaemia	2				x
2	" "	2		x	x	
3	" "	1				x
4	" "	2				x
5	" "	1	x			x
6	" "	1	x			x
7	" "	1		x	x	
8	" "	1			x	x
9	" "	1		x		
10	" "	3				x
11	" "	1		x	x	
12	" "	3			x	
13	" "	2				x
14	" "	2				x
15	" "	1			x	
16	Acute myeloblastic leukaemia	1		x		
17	" "	2				x
18	" "	1				x

A total of 18 children, 15 affected by acute lymphoblastic leukaemia and 3 by acute myeloblastic leukaemia, received the drug intravenously in a daily dose of 1 mg./kg. Each course of treatment was of five days, followed, if the response was not satisfactory, by a second and eventually a third course after a five-day rest period. Two children were at the onset of the disease, 16 were in relapse; six have been treated twice at intervals of several months for successive relapses. All the children in relapse had become resistant to the drugs previously used, such as 6-MP, vincristine, and methotrexate. Daunomycin was well tolerated but induced in several cases a bone-marrow aplasia, which needed to be treated with prednisone and testosterone. Alopecia occurred frequently. Laboratory studies, including liver-function

tests, blood urea nitrogen, serum uric acid, serum electrophoresis, radiographic studies, and E.C.G.s, did not show other toxic manifestations.

Out of a total of 24 patients treated the therapeutic responses were as follows: 2, disease progressed; 5, no change; 11, good partial remission; 6, complete haematologic and clinical remission.—We are, etc.,

Menace of Smoking

SIR,—Your leading article "Menace of Smoking" (23 September, p. 753) is indeed an indictment of the greatest hazard to health of our day, and one which is self-inflicted by indulgence in a noxious habit and one permitted by a succession of indulgent Governments and Ministers of Health.

You table some of the consequences: 30,000 deaths a year in the United Kingdom from cancer of the lung; a large measure of responsibility for the ravages of chronic bronchitis and emphysema; some responsibility for cancer of the mouth, larynx, oesophagus, and possibly pancreas and bladder; increasing evidence of inducing a liability to coronary artery disease and cerebrovascular disease. In other words, smoking bears a measure of responsibility for a majority of the present-day captains of the men of death and disability, and you rightly conclude that the smoking of cigarettes especially is surely the greatest menace to the public health of our time, causing death and disability on a scale reminiscent of the epidemic diseases of earlier centuries.

I have seen no mention of this in the national daily press. It should have been emblazoned across the front pages and immediate Government action demanded to put an end to it. Surely no greater indictment was ever made of the consequences of indulging in "hard" drugs, and yet very stringent laws govern their sale and possession, and even the hours during which alcohol may be consumed on public premises is restricted. Motor accidents account for some mere 7,000 deaths per annum, and yet the use of a motor car is governed quite rightly by an increasing number of restrictions.

You state that if the chances of a smoker contracting cancer "were the same as now, but the interval before death was only some months, it is scarcely conceivable that cigarettes would be marketed at all, or, if they were, that legislation would be long delayed to prohibit them altogether." The time before death is hardly a valid consideration

when death frequently strikes down a man during his working life, and not only from cancer but also from cor pulmonale secondary to chronic bronchitis and emphysema, and from coronary thrombosis. This takes no account of the 30 million working-days lost each year due to chronic bronchitis, much of which is due to smoking, and all of which is greatly aggravated by it. To talk of banning cigarette advertising and educational campaigns is a counsel of despair, as very little reduction of cigarette smoking would result.

I submit that it is the immediate duty of the Minister of Health to induce the Government to take effective steps without delay. The findings of the Royal College of Physicians have been known for some time, and the independent investigation of the tobacco industry has merely served to endorse them this year. I suspect that pressure from the department of Inland Revenue and vested interests, and watering-down of resolve by the many smokers in their midst, has diverted the administration from taking what it well knows to be the right course. In the event, much of the loss of revenue would be made up by the improvement in health and saving of life among the working population, and the economy would also benefit externally, as it would no longer be necessary to purchase tobacco, all of which comes from abroad.

The Minister has recently suggested that managers of places of entertainment should prohibit smoking in the public interest, but this amounted to nothing less than asking those who are public-spirited to hand over their profits to those who are not and who continue to permit smoking. His first step should be to ban smoking in all places of public assembly and on public transport, etc. Already this is done in many large stores in our cities. Neither their staff nor their customers have become nervous wrecks, nor have their sales suffered. This should be followed by the prohibition of smoking in public at all. Another measure which should be adopted is the annual raising by one year of the age below which it is illegal to purchase tobacco.

Such steps would provide only a moderate reduction in consumption, but would be of considerable assistance to a large proportion of smokers who desire to cease the practice, and would greatly increase their numbers. Most important of all, however, it would prepare the public for the only fully effective remedy—the complete ban on the sale of tobacco.—I am, etc.,

Sodium Uptake in Peritoneal Dialysis

SIR,—Dr. M. V. Moriarty (23 September, p. 798) is quite correct in his observation that the removal of large volumes of fluid by hypertonic peritoneal dialysis is an efficient means of depleting the body of sodium. This is well shown in Fig. 4 of my paper (5 August, p. 345) and is indeed emphasized in the text.

However, the urea concentration of the fluid removed by hypertonic dialysis is higher than can be explained on a simple concentration gradient basis.¹ It has been suggested that this is attributable to "solvent drag"

by the large volume of fluid passing through the peritoneal membrane. The purpose of the table to which Dr. Moriarty refers is to indicate that sodium does not behave as urea under these circumstances. The net sodium movement is, as both my paper and Dr. Moriarty's letter suggest, dependent upon the serum sodium concentration and the volume of fluid removed.—I am, etc.,

Place of the Mentally Retarded

SIR,—The single authority responsible for all services for the mentally subnormal advocated by Dr. M. E. York-Moore (23 September, p. 798) would have much to commend it, but one serious, we believe decisive, disadvantage: it would perpetuate the separation of the hospital care of the subnormal from that of all other classes of patients. It is surely indisputable that isolated institutions cannot provide an acceptable standard of medical and nursing care, and cannot offer research on the scale the field of subnormality requires.

As Dr. York-Moore recognizes, there can be no rapid transfer of half the hospital population to local authority accommodation which does not exist. But, if the sensible recommendations of H.M. (65) 104¹ are to be implemented, it is essential to make a beginning by inclusion of approximately 80 subnormal beds per 100,000 population in district general hospitals, and by provision of small hostels which in time would replace the large isolated institutions. We readily concede that there is need for careful consideration of the balance of advantages of an education or a health administration for children under local authorities.—We are, etc.,

Streptomycin, I.N.H., and Thiacetazone

SIR,—A combination of isonicotinic acid hydrazide (I.N.H.), streptomycin, and thiacetazone is frequently employed in India for the treatment of bone and joint tuberculosis. Recently we came across three cases of serious adverse reactions to such therapy.

A 24-year-old female with advanced caries of the spine was treated with a combination of streptomycin (1 g. daily) and Unithiben (I.N.H. 75 mg. and thiacetazone 37.5 mg. per tablet, six tablets daily). The patient developed a generalized erythematous skin rash with marked itching after three weeks on this therapy. The skin eruption subsided after stopping all the drugs. However, a second attempt to administer Unithiben alone led to recurrence of itching and characteristic skin lesions. Routine laboratory investigations at this stage revealed nothing abnormal.

Severe vomiting developed in a 15-year-old female with caries of the spine 12 days after treatment with streptomycin and Unithiben (dosage schedule as above). On withdrawal of Unithiben alone vomiting stopped. In this case there was mild leucocytosis, 10,200/cu. mm., with 6% eosinophils.

A 55-year-old female with caries of the spine, under treatment with streptomycin and Unithiben (dosage schedule as above), developed a generalized macular erythematous skin rash with marked pruritus, jaundice, and mental disorientation. These symptoms appeared approximately five weeks after combined therapy. The skin rash progressed to an exfoliative dermatitis. The patient developed coma and deep jaundice and died a few days later.

In the first two cases the combination of I.N.H. and thiacetazone seems to be implicated. In the last case also the combination might have been responsible for the adverse reactions. Hypersensitivity reactions to I.N.H. are considered to be rare effects.¹ Hepatotoxicity and skin reactions have been reported after thiacetazone.

The concurrent use of I.N.H. and thiacetazone has been reported to be of great promise in the treatment of advanced pulmonary tuberculosis,² but the use of such drug combination may be hazardous in some cases.—We are, etc.,

Dangers of Humidification

SIR,—Dr. W. M. Edgar (26 August, p. 557) rightly draws attention to the risk of contamination of water in Woulfe bottles used for humidification of oxygen. Every variety of container for water used for this purpose is liable to contamination. The risk is not confined to the Woulfe bottle. Plastic containers obscure the turbidity which would otherwise draw attention to grossly contaminated water.

I would therefore, expand Dr. Edgar's important advice regarding the frequent washing and sterilization of Woulfe bottles to include all types of containers used for that purpose, as well as the tubing leading from the container to the mask, catheter, etc.—I am, etc.,

Diabetes Mellitus Complicating Alkaptonuria

SIR,—We are interested in the letter on diabetes mellitus complicating alkaptonuria, by T. W. Wikramanayake (29 April, p. 312). We have come across a case, a male 45 years old, complaining of backache and stiffness of both knee joints and the small joints of both upper limbs of about one year's duration. Biochemical investiga-

tions revealed that he is an alkaptonuric with moderate diabetes mellitus.

The presence in his urine of homogentisic acid is confirmed by extraction¹ and chromatographic identification,² and of glucose by osazone and Selivanoff's tests. Curiously enough, Clinistix failed to detect glucose in this urine. Further investigation has brought to light that this failure of Clinistix was due to the inhibition of peroxidase reaction by homogentisic acid.³

This case seems to be the second to be reported from India since that of Bose *et al.*⁴ where diabetes mellitus and alkaptonuria are coexistent.—We are, etc.,

Psychological Factors and Ulcerative Colitis

SIR,—I have just seen your leading article (1 July, p. 1), the associated paper by Feldman *et al.* (p. 14), and the resulting correspondence. The whole makes clear that in receiving new it is important not to forget old testimony. Which way does the accumulated evidence point?

You refer to the fine pioneer paper of C. D. Murray¹ on the emotional associations of ulcerative colitis, to the delineations of characters of subsequent writers, and to the summary of G. L. Engels.^{2,3} More recently progress in understanding and treating ulcerative colitis has been largely somatic. But the somatic information includes the importance of steroid chemistry and specific sensitivity studies. These in themselves leave the disease wide open psychologically, at the same time bringing it further into line with asthma as a sensitivity disease. A great deal of the observed psychological abnormality of ulcerative colitis can be regarded as emotional hypersensitivity; and the full understanding of the relationship between such states and body chemistry must still be far ahead.

In the meantime I would prefer Halliday's⁴ definition to yours. A psychosomatic disease is, strictly, not one in which the organic lesions are the consequence of emotional disturbances, but one in which the disease as a whole cannot be fully understood until psychological factors are considered. Also, in the hands of some, psychotherapy can (still) improve medical treatment.⁵ Open and inquiring minds must continue to be exercised in this assessment.—I am, etc.,

SIR,—A recent leading article (1 July, p. 1) reviews the controversy concerning the role of psychological factors in ulcerative colitis and warmly endorses a paper by Dr. F. Feldman and others (1 July, p. 14). Careful reading of that paper, however, reveals two disquieting facts: (1) The authors do not draw the conclusions ascribed to them by the leading article. (2) The paper is based on methods to which the reader has no access.

The leading article describes this paper as "one of the few psychiatric studies to discount the importance of psychological factors in the aetiology of ulcerative colitis." The authors, on the other hand, merely "raise the question whether the disease should be regarded as 'psychosomatic.'" This is not only a more cautious conclusion, it is a different conclusion, for they define "true psychosomatic diseases" as those "which must have a psychogenic component as part of the cause, or they cannot exist." By way of comparison they cite "illnesses which appear physical in origin but may be exacerbated, triggered, or hastened by psychogenic factors." These "would be regarded as not 'truly psychogenic' illnesses but ones influenced by psychophysiological factors." This emphasized contrast between "truly psychogenic" and "psychophysiological factors" indicates that they regard psychogenesis, in the strict sense of the word, as a necessary condition before a disease may be regarded as "psychosomatic." This is a spurious issue, for few any longer espouse a pure psychogenic concept of ulcerative colitis. Most hold that ulcerative colitis is a physical process commonly triggered or exacerbated by psychological factors through as yet unidentified physiological processes. Some suggest in addition a degree of specificity about the kinds of background psychological issues most likely to be involved in this chain of events, but this a far cry from invoking pure psychogenesis.¹⁻³

Actually the paper itself is so inexact and inconsistent in terminology as to leave the authors' intent open to many possible interpretations, but this has been true of many papers in the field of psychosomatic medicine. Terms such as "psychosomatic" or "psychogenic" are rarely defined, and many are guilty of using the term "psychosomatic diseases" to designate illnesses in which psychological factors are alleged to play a dominant role. Properly speaking, there can be no such entity as a "psychosomatic disease"; rather there are psychosomatic factors in disease, referring to the interactions, through nervous system activity, between psychological and physiological processes and their resulting influences on somatic systems. The same objection may be raised to the use of such expressions as "genetic disease" or "biochemical disease." For example, the demonstration of a genetic factor underlying deficiency of glucose-6-phosphate dehydrogenase does not justify designating as a "genetic disease" the haemolytic anaemia that sometimes ensues upon interaction with certain drugs. One might equally well call sunburn a "genetic disease" in the light of the role of the genetic factors influencing pigment formation. Genetic factors and psychosomatic factors are probably significantly involved in the pathogenesis of many diseases, and with appreciation of the multifactorial aetiology of disease it is time to put an end to such simplistic either/or concepts as are promulgated in both the paper and the leading article.⁴

The second criticism is a grave one. On the surface the authors appear to have evolved a highly original and sophisticated methodology, but unfortunately they provide no details. Briefly, the primary data consist of two or more

interviews averaging a total of 10–12 hours for each patient, but no mention is made how such data were recorded or handled. One hundred and eight patients, 34 with ulcerative colitis and 74 controls, were studied over a period of 22 months. In that period 65 psychological variables, bearing on seven criteria selected as necessary to prove psychosomatic disease, were judged on a five-point scale for each of the 108 patients. Now this is an exceedingly complex undertaking, even when utilizing tests with established reliability. Yet we are not told what the 65 variables are, how they were selected, how their relative values *vis-à-vis* the seven criteria were established, or what the judging procedure was; indeed, none of the facts required to evaluate the results. The only reference is to an unpublished 200-page handbook. Besides not knowing what was being scored, one may also question whether a task of data analysis involving a total of from 7,000 to 70,000 judgements of personality variables (estimated on 65 judgements for each of 108 patients or for each of 1,200 patient-interview hours) could be accomplished in such a short time without sacrificing the standards required for this type of psychological measurement.

When subjected to the cold glare of critical scrutiny one is forced to say that the leading article drew an unwarranted conclusion from a study which posed the wrong question, applied an unknown method, and obtained a dubious answer.—I am, etc.,

Paraproteins and Bence Jones Protein

SIR,—I was intrigued by Dr. J. R. Hobbs's outstanding contribution to the study of paraproteins (16 September, p. 699). However, there was one point which I did not understand, and this seems to me to explain a discrepancy. The statement has been made (Fig. 2) that "patients producing Bence Jones protein only . . . present with lower production rates than the others, suggesting differentiation of their tumours," whereas in the discussion it is stated that "an increase of light chain excretion reflects an inefficient process and probably implies that the synthesizing cells have lost their differentiation." As I understand it,¹ the quantity of Bence Jones protein in the urine cannot be taken as an indication of the rate of production, since catabolism of Bence Jones protein occurs in the kidney, and especially is this so when there is normal renal function.—I am, etc.,

Diabetic Lipaemia

SIR,—I was interested in the letter on diabetic lipaemia (26 August, p. 557). Perhaps this condition is not as rare as was

previously thought in young diabetics. I wish to record a recent case.

A 12-year-old girl, a known diabetic for six months, had been controlled on 42 units of lente insulin daily. On the day of admission she had received her insulin and was complaining of faintness and vomiting.

On examination she was ketotic and dehydrated. Urine sugar was 2% and acetone + + +. Her maximum blood sugar was 253 mg./100 ml., serum sodium 110 mEq/l., the serum potassium 4.6 mEq/l., and serum bicarbonate 3.5 mEq/l. On venepuncture the blood was pink and greasy. The serum was milky in appearance.

She was treated with soluble insulin and intravenous infusion. Her serum cholesterol was 830 mg./100 ml. on the first day, and on the third, seventh, and fourteenth days was 225 mg./100 ml., 272 mg./100 ml., and 172 mg./100 ml., respectively.

This case of diabetic lipaemia occurred in a girl well until 24 hours prior to admission, and cleared after two days. She has remained well since, on only 60 units of lente insulin daily.

I wish to thank Dr. I. Kessel for permission to report this case under his care.

Sales Promotion

SIR,—A good deal of criticism is being levelled at the pharmaceutical industry on account of the volume of its publicity, and I must confess that I am sometimes irritated by the amount of advertising in its various forms that passes through my hands. However, I am beginning to glimpse a tendency on the part of some firms to provide the general practitioner with material of practical value, and to help stimulate informed use of their product. I regard examples of programmed learning and diagnostic handbooks of real value, and more recently I was offered, and readily accepted, some disposable proctoscopes, for which I shall certainly find real use.

If this is a trend for the future I would welcome it as a method of improving the understanding between doctor and manufacturer, and wonder if my colleagues have any views upon it.—I am, etc.,

BASIL MARSHALL.
Blechingley,
Surrey.

Drug Names

SIR,—While many will agree that the Sainsbury Committee is wise not to recommend the nationalization of the pharmaceutical industry, it seems unfortunate that they are contemplating the abolition of brand names for future drugs.

Surely anything that assists identification in the prescription of drugs outweighs any consideration of commercialization in the industry and helps to avoid misinterpretation by pharmacists of the written prescription.

With many years' experience in the promotion of drugs in this industry, such a proposal appears to me to point to a lack of consideration of all the factors concerned. The British pharmaceutical industry is in fact way ahead of any other country in the world, and this, in my opinion could do nothing but harm to it.—I am, etc.,

Reprints: Who Should Pay?

SIR,—The problem of dealing with requests for reprints, which has been raised in your correspondence columns (16 September, p. 740), is not a financial one for most of us; the difficulty is to find time to answer requests when already pressed to cope with routine work and one's research activities without secretarial help. The vast majority of inquiries come from the U.S.A., and often seem to be needed merely to add to a library file. The nominal sum now charged for a photostat copy of an article should make routine collection of reprints unnecessary; if everyone ignored requests not accompanied by a personal letter the practice would soon die out.—I am, etc.,

Hornchurch,
Essex.

S. E. BROWNE.

Doctors in the Armed Forces

SIR,—The Association undertook to inform medical officers in the armed Forces of progress in negotiations on their pay structure. There has been little or no news for some time; can we infer that an impasse has been reached and that the black-listing by the Association of the armed Forces medical services has proved ineffectual in the face of the defence cuts?

Service medical officers are in a very difficult position; there must be many like myself who, enjoying the life and believing that it enables them to practise good medicine, nevertheless feel considerable anxiety over their future careers and financial prospects and must soon decide between remaining in the Services and seeking the greater financial rewards and security of civilian life. The Prime Minister has made no secret of his need to foster recruitment to the National Health Service at the expense of the armed Forces (*Supplement*, 18 February, p. 50); but how many of us would willingly transfer from frying-pan to fire? Besides, for the ex-regular officer, re-entry to the N.H.S. would involve in many cases loss of pension rights unless considerable superannuation back payments were made.

We could be materially assisted in these decisions by information from the Association of our future prospects. Can we, for example, expect any consideration in the biennial pay review due next year? Or will we again, by dilatoriness, have no link either with the executive or with doctors in the N.H.S.? If negotiations are to reopen have we any proposals to make? I know of no efforts by the Association to canvass the views of serving officers.—I am, etc.,

Co. Derry.

R. P. DOHERTY.

B.M.A. as a Negotiating Body

SIR,—The time is surely much closer when the British Medical Association must establish fully democratic representative machinery for junior doctors. It was thus very encouraging to read the clearly defined aim of the Junior Hospital Doctors' Association in Dr. J. H. Briggs's letter (16 September, p. 741).

So long as junior doctors, especially those in hospital practice, feel that they have no proper voice within the B.M.A. they will refrain from joining its ranks.

It is to be hoped that a satisfactory conclusion will soon be reached in the talks currently being held between the B.M.A. and the J.H.D.A. Then and only then will it be worth while for the B.M.A. to hold a vigorous membership campaign among colleagues in the field of junior hospital practice.—I am, etc.,

London E.15.

CHRISTOPHER BOLT.

Christmas Gifts Appeal

SIR,—I should be grateful if you would once more allow me to make known in your columns the Christmas gifts appeal that is made annually by the Royal Medical Benevolent Fund. This special gifts fund is distributed to the hundreds of beneficiaries at Christmastide, when the little extra makes such a welcome increase to their happiness. We feel sure that the profession will make a generous response to this appeal.

Contributions marked "Christmas Gifts" should be sent to the Royal Medical Benevolent Fund, 24 King's Road, Wimbledon, London S.W.19.—I am, etc.,

ZACHARY COPE,
President,
Royal Medical Benevolent Fund.
London S.W.19.

Points from Letters

Mercury Perchloride in Surgery of Bowel Cancer

Mr. C. L. HEANLEY (Worthing, Sussex) writes: The use of mercury perchloride to prevent wound contamination by malignant cells has been shown to reduce implants statistically. How does it work? It is interesting when one has cut excess skin, when skin grafting, to soak pieces of excess skin in varied solutions, and reapply to the donor surface with a control piece. After the graft has been in transient contact with spirit, cetrimide, or gum mastiche it is killed, whereas soaking for five minutes in 1:4,000 or 1:1,000 mercury perchloride does not kill the graft. One can also graft over Hibitane (chlorhexidine) powder.

It would appear that mercury perchloride in these strengths will not kill normal epithelial cells; however, this is no proof it will not kill "cancer" cells.

Consultants' Views of General Practitioners

Dr. D. M. MACMANUS (London S.W.1) writes: I have practised as a general practitioner for 53 years, and in that long time I have learned tolerance and to respect the opinions of other doctors, even if I didn't agree with them. The infinite variety of man is shown among doctors as among other professions. I have employed very many consultants and sent very many patients to consultants at their hospitals, and by an enormous majority they have proved exceedingly helpful, and always keep me up to date with the patient's condition. I do not always agree with the consultant's opinion—I like to stand on my own feet—but he is usually, not always, right. I have met some consultants for whom I have had no respect.

Again, the majority of general practitioners are very hard-working, conscientious individuals, and their main consideration is for their patient. They are immensely dependent on the consultant, and he does not often realize his indebtedness to them. This bickering is really stupid. All we doctors wish for is the welfare of our patients. To quarrel among ourselves about who does what is nonsense. It takes all sorts to make a world, and please let us be tolerant and understanding of each other.

Obituary Notices

Sir JAMES LEARMONTH, K.C.V.O., C.B.E., LL.D., M.D., CH.M., F.R.C.S.
F.R.C.S.ED., F.R.A.C.S., F.A.C.S., F.R.F.P.S.GLASG.

Sir James Learmonth, formerly professor of surgery and regius professor of clinical surgery at the University of Edinburgh, died on 27 September. He was 72.

James Rognvald Learmonth was born at Gatehouse, Kirkcudbright, on 23 March 1895, and received his early education at Girthon School and Kilmarnock Academy.

(Walter Stoneman)

His studies were interrupted by the first world war, during which he served with the King's Own Scottish Borderers. On demobilization with the rank of captain he entered Glasgow University, graduating M.B., B.Ch. with honours in 1921, and was awarded the Brunton Memorial Prize

for the most distinguished graduate in medicine for the year. After early house appointments at the Western Infirmary, Glasgow, he worked for a time as assistant to Professor Archibald Young, first at Anderson College of Medicine, Glasgow, and later at Glasgow University. In 1924 he was awarded a Rockefeller medical fellowship, and spent a year at the Mayo Clinic in the United States, returning to Glasgow, where he took the Ch.M. with high commendation in 1927, and in the following year was elected F.R.C.S.ED. He went back to the Mayo Clinic in 1928 as a neurological surgeon on the staff of the clinic and associate professor of neurological surgery in the University of Minnesota. He returned to Scotland in 1932 as regius professor of surgery at Aberdeen. In 1939 he was appointed professor of surgery at the University of Edinburgh, and in 1946 regius professor of clinical surgery. In 1951 he was appointed a member of the Medical Research Council, and in 1954 Sir Arthur Sims Commonwealth Travelling Professor of the Royal College of Surgeons of England.

Many honours and distinctions came his way. He was appointed C.B.E. in 1945 and was made a Chevalier of the Legion of Honour in 1950. In recognition of his distinguished contributions to surgical science he was awarded the Lister medal in 1951. Having been called in November 1948 to attend King George VI in his illness, in 1949 he was appointed a surgeon to the King in Scotland, and the K.C.V.O. was conferred on him in the same year. He was a surgeon to the Queen in Scotland from 1952 to 1960, and was extra surgeon since this time up to his death. His outstanding work was recognized by the award of honorary degrees from the universities of Oslo, Paris, Sydney, and Strasbourg, in addition to those from Glasgow, Edinburgh, and St. Andrews. He was elected an honorary fellow of the Royal

College of Surgeons of England in 1949, and of the American College of Surgeons in 1950. In 1954 he was elected an honorary fellow of both the Royal Australasian College of Surgeons and of the Royal Faculty of Physicians and Surgeons of Glasgow. A member of the British Medical Association, he was vice-president of the Section of Surgery at the Annual Meeting in 1936, and president of the Section in 1939.

On his retirement from Edinburgh University at the end of September 1956 the title of Professor Emeritus was conferred on him.

He married in 1925 Charlotte Newell Bundy, of St. Johnsbury, Vermont, U.S.A., who survives him with a son and a daughter.

D. M. D. writes: To work with James Learmonth was to see the impact of a fine brain and a powerful character on the many problems associated with running a busy university surgical unit. He was an outstanding scholar with an abiding love of books, a quality no doubt derived from his father, who was a schoolmaster in Galloway. He was also a much-loved doctor whose patients spoke of him with warmth and affection. An imaginative administrator, he established during the tenure of his chair in Edinburgh university departments of urology, plastic, thoracic, and paediatric surgery, each of which is now internationally famous. A shy man with an austere manner, he was warm-hearted and infinitely thoughtful to those near to him. Inspiring loyalty in others, his loyalty to his friends was legendary, and many surgeons everywhere have cause to be grateful to him for his help and advice.

He received the highest honours from all over the world, and though he valued them he valued far more the free interchange of ideas which association with colleagues and friends gave him. Nothing delighted him more than to talk over research projects with his staff. His criticisms were outspoken but fair and he recognized that failure was irrelevant; to try was the important thing. A man of the highest integrity, he never shirked an unpopular decision if it was the right one. He ranks with William Mayo, Harvey Cushing, and Geoffrey Jefferson as one of the surgical giants of our time.

A. L. writes: Sir James Learmonth retired from the chair of surgery at Edinburgh in 1956, when he said he had occupied it for as long as any man ought to hold so important a professorial office. Few developments in surgical teaching pleased him more than the formal incorporation in the department of surgery 10 years previously of subdepartments in specialties recently and incompletely separated from general surgery. The staff of these departments had a peculiarly close clinical and academic relation with him. He was severe in his criticism and generous in his appreciation of their work, and no comment ever lost him a fraction of the respect and affection in which he was held. He gave, and received, complete loyalty. As a forum

for surgical discussion he instituted Saturday morning departmental meetings. These began on the first stroke of 9 o'clock. One or other unit acted as host and presented aspects of its work—clinical, experimental, or literary. Many remember from these occasions something of their colleagues' contribution, but far more of Sir James's devotion to the interests of the University, his gentleness and kindness to patients, his deep concern for the welfare of his juniors, his ability to bring common sense to bear on a clinical or administrative problem, and his undeviating honesty.

J. McM. writes: James Learmonth's distinguished career began where he was born, in the tranquil and lovely valley of the Fleet in Kirkcudbrightshire. He was leaving the little local parish school of Girthon about the time I entered. We were both much influenced by his father, who was our strict and comprehensive schoolmaster, passing rich on perhaps £140 a year; his erudition and scholarship seemed all-embracing, and in later years we often talked of his influence in teaching us how to enjoy deep study. Running some years behind, I watched this handsome, brilliant student sweep forward in his medical career. He published papers, while still a student, on blood-group inheritance and on wind-speed measurements in relation to gas warfare in the first world war. Though chastened somewhat by his combatant war experience, he graduated with all honours and moved rapidly into his successful career in surgery. At one time his future seemed to be in America, where he had found a place on the staff of the renowned Mayo Clinic, but finally loyalty to this country prevailed and he returned to Aberdeen as regius professor in surgery, moving later to the larger responsibility of Edinburgh in succession to Sir David Wilkie. His continuing researches on the detailed anatomy of the sympathetic system, and on the innervation of the bladder, made him the ideal academic surgeon of his time. His determination to hold the reins of academic leadership imposed the strains of wide-ranging responsibility, and made exacting demands not only on him but also on his staff and colleagues. His aim was always towards an ideal, and any failures to achieve his objective told heavily upon him. Like his father, he could be an embarrassingly strict disciplinarian, but as a teacher he was superb. When he was off the beat and more relaxed discussion on university responsibility could be fruitful and challenging, and a last visit to him a day or two before his death found him deep in contemplation and lucid exposition of the problems of academic development that lay before us. His influence and example will be long-lasting.

A Glasgow colleague writes: Some years after he had retired James Learmonth was elected an Assessor of the General Council on the Court of the University of Glasgow. Always an honoured and welcome visitor to his Alma Mater, his appointment gave universal pleasure and he himself derived a very

deep and lasting satisfaction in the duties of this office. Those whose privilege it was to come most in touch with him in his new work soon realized that all the fine qualities of earlier days were not only undimmed but indeed enhanced by the measure of detachment he imposed on himself in his judgements and advice. Such restraint was a part of the way of life he set for himself and which found its highest expression in the selfless, disciplined behaviour of his last days.

**LEONARD COLEBROOK, D.Sc., M.B.
B.S., F.R.C.S., F.R.C.O.G., F.R.S.**

Dr. L. Colebrook, formerly director of the Medical Research Council's Burns Unit at the Birmingham Accident Hospital and pioneer of studies of wound infection, of the sulphonamides, and of the modern treatment of burns, died on 29 September. He was 84.

Leonard Colebrook was born in Guildford on 2 March 1883 and was educated at Guild-

ford Grammar School; the High School, Eastbourne; Christ's College, Blackheath; and St. Mary's Hospital, London, graduating M.B., B.S. in 1906. After graduating he continued to work as one of the brilliant team of bacteriologists which included Sir Alm-

roth Wright and Sir Alexander Fleming. He was later to publish a biography of Wright, whom he greatly admired, in 1954. Hearing Colebrook speak of him one would not have suspected by how much the disciple had outstripped his great teacher. During the first world war Colebrook went to France as a member of a research team studying wound infection. They looked for a treatment which would attack the infecting organism without damage to the body's own defences. After a further period of work at St. Mary's Hospital for the Medical Research Council, which he joined in 1920, Colebrook seized upon the possibility that the sulphonamides might fulfil this role, and he was the first to establish their life-saving value in puerperal sepsis. This work was done in collaboration with Dr. M. Kenny at Queen Charlotte's Hospital, where Colebrook was honorary director of research from 1930 to 1939.

At the outbreak of the second world war he was commissioned as colonel, and appointed bacteriological consultant to the Army in France. Serious problems were then being presented by burns, and, seeing this as a further field where wound infection was of the utmost importance, in 1942 Colebrook joined a Medical Research Council team in Glasgow which produced the now classical M.R.C. special report *Studies in Burns and Scalds*. The Accident Hospital in Birmingham was starting at this time, and in 1944 Colebrook accepted an invitation to organize and direct its new burns unit. Already famous for his work on wounds and on puerperal sepsis, he now founded a new

worldwide reputation in the care of burns. He introduced aseptic dressing techniques, full use of modern drugs, and exploitation of the developing techniques of early skin grafting.

Honours came to him, and in 1945 he was made a Fellow of the Royal Society. He was elected to the honorary fellowship of the Royal College of Obstetricians and Gynaecologists in 1944, to that of the Royal College of Surgeons of England in 1950, and in the same year an honorary D.Sc. was conferred on him by Birmingham University. At the 14th British Congress of Obstetrics and Gynaecology, held at Oxford in 1955, Colebrook was presented with the Blair Bell medal for his work on puerperal sepsis, begun at Queen Charlotte's Hospital in 1936. In 1962 the council of the Royal Society of Medicine awarded him the Jenner Medal.

"Coli's" great humanity and unwillingness to remain passive in face of unnecessary suffering fired a continued interest in the prevention of burning accidents. By publications, lectures, and personal approaches he drew attention to the need for action. His stimulus was behind the later legislation for protection, particularly of children, by guarding of fires and the use of safer fabrics. It was a great joy to him in his later years to see that these efforts were beginning to show results.

His colleagues and associates greatly appreciated his penetrating but kindly understanding of their problems, and to a wonderful extent these abilities were retained to the end. In the trials of advancing years he was supported with great understanding by his wife, Vera, to whom, as well as to her beloved husband, tribute is due.—J. P. B.

A. B. PORTEOUS, M.D., D.P.H.

Dr. A. B. Porteous, formerly consulting bacteriologist at St. Mary's Hospital, Paddington, London, died on 21 September after a long illness. He was 80.

Arthur Borland Porteous was born on 22 October 1886, and received his medical education at St. Mary's Hospital, London, graduating M.B., B.S. in 1910. He held

early appointments at St. Mary's Hospital, and was influenced by the strong tradition in pathology there at the time. At the outbreak of the first world war he joined the R.A.M.C. as a general medical officer, later being graded as a bacteriologist, and worked as a member of the team at Boulogne on war wounds and gangrene among the troops. After demobilization with the rank of captain, when Sir Almoth Wright reassembled his group at St. Mary's after the war, Porteous became a diagnostic bacteriologist, and interested himself in public health. He took the D.P.H. in 1920, and proceeded M.D. the following year. He was

[Bassano & Vandyk]

soon one of the small number of clinical pathologists in practice between the wars. He made no academic claims, and published little, but he provided a service to his clinical colleagues, within the limitations of the techniques of the period, that was well above the average. His confidence, his physical stamina, and his technical competence, particularly with needle and syringe, provided the sort of help needed in private house or nursing home.

Porteous had a remarkable flair for briefing himself on problems as they occurred. He was able to tackle not only bacteriology but haematology, transfusion work, and the necessary minimum of chemistry. In a generation when all pathologists appeared to have nicknames, his versatility and ubiquity earned him the modification of his own name to "Proteus." With the opening of chest clinics in the London area he became tuberculosis officer for Paddington, and ran a clinic first in the basement of the Wright-Fleming Institute and later near Westbourne Grove in one specially built there. He was always popular with his patients, and retained many of them as friends. If his equals occasionally found him pugnacious, his juniors, the technicians, and the students found him kind, and he was one of the most useful persons to turn to when faced with a difficult venepuncture or similar problem. He took considerable interest in the student life, particularly in the Yacht Club, and remained a keen sailor on the Thames until recently.

During the second world war his position as bacteriologist to the Boroughs of Paddington and Kensington made him the obvious person to take charge of public health bacteriology for the St. Mary's sector. This he did in company with Dr. M. Y. Young, first at King Edward Memorial Hospital, Ealing, and later back at St. Mary's. After the war he returned to private practice, and continued in it until his retirement due to increasing ill-health only about three years ago.

He is survived by his second wife and by his son, Dr. A. C. Porteous.—W. H. H.

W. WEINER, M.D., F.C.PATH.

Dr. W. Weiner, who directed the Birmingham Regional Blood Transfusion Service until the end of October of last year, died on 31 August after a long illness. He was 68.

Walter Weiner was born in Austria on 14 June 1899. He studied medicine at Prague, graduating M.D. in 1924. He was then appointed a clinical assistant in the university clinic, and he also practised as a physician. During this time he started to develop his interest in haematology, particularly in morphological haematology. Just before the second world war he came to England, where after a period in practice and as a medical officer in a sanatorium he joined the R.A.M.C., with whom he saw service in Africa. After demobilization in 1946 he was appointed deputy director of the Birmingham Regional Blood Transfusion Service, and when the physician in charge of the Service retired Dr. Weiner took over those duties.

Under Dr. Weiner's guidance the Service developed rapidly, although it operated in unsuitable accommodation. It was moved from one very old building to another that

was slightly less inconvenient, but it became apparent that a much more specialized building was required if the Service were to function efficiently. Much of Dr. Weiner's time in his last years as director was spent in designing and supervising the building of the new Blood Transfusion Service building, and the Regional Hospital Board encouraged him to stay in charge until it was running smoothly in its new headquarters. Soon after the new premises were occupied it was obvious that the thought he had put into its design had produced a very practical building.

Apart from the routine provision of blood products, which were always being augmented when the need became apparent for some new application of blood transfusion services, Dr. Weiner built up a very well organized antenatal serological screening service, and from this developed his interest in the protection of the susceptible women with antirhesus antisera. In spite of his preoccupation with the running of his Service he was a very active bench worker, and became particularly interested in the problem of acquired haemolytic anaemia. He will be best remembered for his classification of autoimmune anaemias, and for the technique which he evolved to elute antibodies from sensitized red cells. He became a Fellow of the College of Pathologists in 1964.

Dr. Weiner was a welcome visitor in many hospitals in all parts of the region, where he would go to see patients and specimens if he were asked. He was a man of great integrity who did not accept dogma for the sake of conforming. All those who knew him had hoped that he would be able to continue his research work after retiring. Unfortunately his retirement was marred by the illness which caused his death, regrettably before he had completed writing a book which was to have contained the data he had accumulated on the autoimmune anaemias.

He leaves a widow and a son.—K. B. R.

G. LISSANT COX, C.B.E., M.A., M.D.

Dr. G. Lissant Cox, formerly chief tuberculosis officer to Lancashire County Council, died at his home in Church Stretton, Shropshire, on 27 September. He was 88.

George Lissant Cox, son of George H. Cox, J.P., was born in Birkenhead on 14 September 1879, and was educated at Abbotsholme School, Derbyshire; Christ's College, Cambridge; and Liverpool University, qualifying with the Conjoint diploma in 1906, and graduating M.B., B.Ch. the following year. After early appointments at the Royal Infirmary, Liverpool, he became honorary assistant physician at the Liverpool Consumption

(Lenare)

Hospital, and assistant lecturer in pathology and bacteriology at Liverpool University. He proceeded M.D. in 1910, and some two years later he became central tuberculosis officer to Lancashire County Council.

Lissant Cox was a member of the standing advisory committee on tuberculosis of the Minister of Health, chairman of the Joint Tuberculosis Council of England and Wales, an active member of the National Association for the Prevention of Tuberculosis (now the Chest and Heart Association), and a member of the editorial board of *Tubercle*. He was chairman of the Preston Division of the British Medical Association in 1927-8, and vice-president of the section of tuberculosis at the Annual Meeting in 1929.

His valuable work in the tuberculosis service was recognized in 1944, when he was appointed C.B.E., two years before his retirement in 1946. In 1959, at a dinner held on his 80th birthday, his friends and colleagues of the Tuberculosis Association presented him with a book and the Varrier-Jones memorial medal for his outstanding work in the field of tuberculosis.

In 1919 he married Sarah Marguerite Howarth, and they had a son and two daughters.

A. D. writes: I had known Lissant Cox for over 60 years. He was educated at Abbotsholme School, of which in later life he became a governor; at Christ's College, Cambridge; and, for clinical work, at Liverpool, where his father was well known in commercial and political circles. After resident appointments at the Liverpool Royal Infirmary he was elected to a fellowship in pathology, where he worked with Professor Sir Rupert Boyce and Professor Ernest Glynn. At this time he was assistant pathologist to the Royal Infirmary, which implicated him in the diagnosis, in 1910, of one of the last cases of human plague to occur in Britain.

He was attracted early to the study of chest diseases, and was appointed to the honorary staff of the Consumption Hospital, Liverpool. All seemed set fair for a successful career as a consulting physician in Merseyside. But the Health Insurance Act with its provision for the treatment of the tuberculous insured (extended by later legislation to cover the entire population) was about to come into operation, and changed the direction of his career. Among the profession there was general hostility to this Act, but Cox and his father were strong supporters of Lloyd George's policies, and that no doubt was the reason why he applied for and obtained the post of central tuberculosis officer for the Lancashire County Council. His friends told him that it was professional suicide, but it led eventually to national, and even international, acclaim.

Lancashire's tuberculosis scheme became the model which other large local authorities tried to emulate, but in which they never quite succeeded. He had a better clinical background than most of the other early tuberculosis officers, and a strong and wealthy county council behind him. He believed in decentralization, and gathered around him an extremely able team, who later were snapped up by other local authorities, and they spread the "gospel according to Cox." He co-operated easily with the county boroughs of Lancashire, overcame the jealousies which so often cause disharmony, and arranged many joint appointments and joint use of premises. He was responsible for planning the sanatoria provided for the county.

He was in great demand on the national level, and was an active member of the Council of the National Association for the Prevention of Tuberculosis, which is now the Chest and Heart Association; he was also a member of the Minister of Health's advisory committee on tuberculosis, and chairman of the Joint Tuberculosis Council for England and Wales. An interest which he retained long after his retirement was membership of the editorial board of *Tubercle*. The Ministry of Health always sent foreign visitors seeking information about antituberculosis work to see Cox, and to study the Lancashire scheme. He received the C.B.E. in 1944, and the Varrier-Jones gold medal in 1959.

He was an enthusiastic angler, and went to fish in Loch Maree every year. In 1922 he was involved in a virulent outbreak of botulism at the hotel where he usually stayed, but on this occasion he had not booked early enough and was in a neighbouring one, and was called in to help with the dying guests.

His retirement over 20 years ago was from medical work to fruit farming. His farm was at Church Stretton, Shropshire, where he specialized in apples. As a grower of Cox's Orange Pippins his name was an asset, and it intrigued his friends to see vans being driven along the Shropshire lanes painted on each side, "Lissant Cox, Fruit Grower." But the fruits of his professional work will remain for many a year. Tuberculosis is not now the problem it was, and it needed a man of the stature of Lissant Cox to tackle it when it was at its zenith. He was the last survivor of the original tuberculosis officers, and the greatest of them all.

He had a great sense of humour, and the loudest and most infectious laugh I have ever heard.

He had a happy family life, and great sympathy will be felt for his widow and three children.

S. BOLTON, M.D., F.R.C.S.E.D.

Dr. S. Bolton, formerly general practitioner and consultant surgeon, died on 15 September in the Royal Halifax Infirmary, the hospital in which he had worked as honorary and consultant surgeon for nearly 40 years. He was 78.

Stuart Bolton was born at Enstone on 22 December 1888, the son of an Oxfordshire farmer, and one of nine brothers and sisters, three of whom entered the medical profession. He was educated at Burford Grammar School, and graduated M.B., Ch.B. at Edinburgh University in 1912. His first house appointment was as house-surgeon to Charles Cathcart, and this probably influenced his career, because there followed a period as lecturer and demonstrator in the anatomy department. A study of comparative anatomy ended in a thesis which in 1915 gained for him an M.D. and the Goodsir Memorial Fellowship and prize. Soon after his marriage he went to help his overworked friend and Edinburgh contemporary Charles W. Graham, who was in practice in the Shetlands and attached to the Royal Navy as surgeon and agent. Based on the small Gilbert Bain Hospital in Lerwick, they made an ideal surgical partnership. Daily and often nightly they were in boats of all kinds.

They had no x-ray machine, no ambulance, and no regular anaesthetist. It was a hazardous and always exciting life. In 1923 he returned to Edinburgh and took the F.R.C.S., coming to Halifax the same year as a partner in a general practice. He was appointed honorary surgeon to Halifax Royal Infirmary in 1926, and for the rest of his professional life he filled this dual role of general practitioner and surgeon, this position being confirmed in 1948 with the beginning of the National Health Service.

Although a general surgeon, he developed interest later in obstetrics and gynaecology, and he was responsible for the formation and growth of the midwifery department and school at the infirmary, which was later incorporated—inevitably, and to his disappointment—in the larger unit at the General Hospital. He retired from his appointment in 1955 but retained his interest in the hospital service. He was a member of the management committee for many years, and was particularly concerned in the development of the geriatric and allied social services in the town. He will be remembered also for his love of the humanities and his exceptionally wide range of interests, which stimulated all those with whom he came in contact and made him what he was—a family doctor.

His first wife died in 1959, and after a few lonely years he married a second time. To his widow, and to his son and daughter, we extend our sympathy.—J. H. F.

J. H. PALMER, M.B., CH.B., D.M.R.D.

Dr. J. H. Palmer, consultant radiologist to Aberdeen General and Special Hospitals, died suddenly at his home in Cults on 18 September. He was 38.

James Hugh Palmer was born in Kingussie on 7 February 1929, and was educated at Kingussie School, where he was the MacGruer Dux medallist. He received his medical education at Aberdeen University, graduating M.B., Ch.B. in 1953. After early appointments as house-surgeon at the Royal Northern Infirmary, and house-physician at Raigmore Hospital, Inverness, he was appointed regimental medical officer to the 19th Field Artillery Regiment, Royal Artillery, with whom he saw service in Germany and Hong Kong, and active service in Korea. On demobilization he began a career in diagnostic radiology in Edinburgh, taking the D.M.R.D. in 1958. After a brief spell in Barnet General Hospital he returned to Aberdeen in 1959 as a senior registrar, and four years later was appointed consultant to the Aberdeen General and Special Hospitals.

In his short career Palmer made a wide contribution to radiology in the north-east of Scotland. At the Royal Infirmary he devoted much time to radiology of the urinary tract. He had sole charge of the x-ray department at the City Hospital, did regular sessions at the Royal Aberdeen Hospital for Sick Children, and made many visits to the Orkneys and Shetlands. His humane attitude to patients, his skilful approach to his subject, his modest manner, and his dry sense of humour gained him respect and popularity among his hospital colleagues. Jimmy Palmer was a congenial colleague and companion who had a real zest for life. He loved all

kinds of gadgets from x-ray apparatus to fast cars. He had a ready wit, was a generous host and guest, and loved, above all, his family and friends, to whom he was invariably kind, courteous, and considerate.

In 1954 he married Elaine Yule, a nursing sister, and when a few years later his career was interrupted by a serious abdominal illness her help was a major factor in his recovery to health. His sudden and premature death came as a profound shock to all who knew him, and our deepest sympathy is extended to his devoted wife.—D. A. E. M. and L. E. G.

R. A. J. STANFORD, B.Sc., M.B., B.Ch. B.A.O., L.M.

Dr. R. A. J. Stanford, a general practitioner in Scunthorpe, Lincolnshire, died on 14 July. He was 58.

Russell Aubrey John Stanford was born in India on 12 September 1908. He was educated at Blackrock College, and entered University College, Dublin, where he took the B.Sc. (Pathology) in 1931, and graduated M.B., B.Ch., B.A.O. in 1933, later in the year taking the L.M. at the National Maternity Hospital, Dublin. He held early resident posts at St. Vincent's Hospital, Dublin, and later was honorary assistant physician and pathologist at the Beckett Hospital, Barnsley. He settled in general practice in Scunthorpe, Lincolnshire, where he established a highly successful group practice. His medical interests were widespread. Besides his extensive work in general practice, he was deputy medical officer of health to Scunthorpe Corporation for 12 years, medical officer to Scunthorpe United Football Club for six years, and medical officer to Firth-Brown's steel works. He was also a member of Scunthorpe Hospital Management Committee for some years, and an active member of the Scunthorpe Division of the British Medical Association, serving as chairman in 1949–50.

Outside medicine his interests were equally widespread, and he was well known at all the social activities in Scunthorpe and North Lincolnshire. For many years he was an active member of Rotary, and in 1959 he visited America representing Rotary International for District 102. A Roman Catholic, he was keenly interested in all functions of the Catholic community, particularly education and charitable activities. He was a much liked and respected public figure in the area, and his early and untimely death will leave a gap in the medical and public life in North Lincolnshire.

Russell was a big man, in both physical and mental stature. He had a lively and pleasant personality, and displayed a deep and personal interest in everyone he met. He kept himself abreast of all the various aspects of modern medicine, and could be relied upon to be up-to-date in the latest medical developments in diagnosis and treatment. His enthusiasm and love of life made him a wonderful and lively companion, particularly when he attended the rugby international matches. It was always "open house" at "Donaghadee," his home, and one could be certain of a warm welcome, wonderful hospitality, and entertaining conversation. Towards the end, when facing a major opera-

tion, he showed, as one might have expected, deep and profound resources of courage, cheerfulness, and exemplary fortitude.

We offer our sincere sympathy to his wife and family in their sad loss.—J. R. C.

F. J. BENTLEY, M.D., F.R.C.P., D.P.H.

Z. A. L. writes: Frank Bentley (obituary, 30 September, p. 869) was a man of wide interests, all of which he pursued with inspiration and enthusiasm, and whatever he decided to do he did well. He was a kind, modest, generous, and public-spirited man, giving his advice unostentatiously in the form of a question. Pulmonary tuberculosis was his main interest. His personality led him to work in the public health service in the first part of his career, chiefly as an administrator in the reorganization of the tuberculosis services of the L.C.C. During this time he kept in close touch with clinical medicine. His report to the Medical Research Council on artificial pneumothorax in 1936 summarized and evaluated this most important therapeutic weapon against pulmonary tuberculosis between the two wars. Later he published the first comprehensive paper on mass radiography in this country in the pages of the *B.M.J.* in 1940, which was the outcome of his work with the large number of soldiers who had joined up at the outbreak of war, concealing their tuberculous past, but were invalidated from the Services because of recrudescence of their lesions.

The most creative and fruitful part of his life were the 12 years spent at High Wood Hospital after 1947. Here he had the opportunity to follow the course of tuberculosis in a community of 250 growing children during the difficult postwar years, and to experience the influence of increasing affluence and the newer antibiotics, together with modified therapeutic techniques, on the natural history of tuberculosis in childhood and adolescence. The outstanding success of this period can be summed up by the fact that, at the time of his appointment to High Wood, sanatorium beds had to be hired in Switzerland, and that twelve years later his own hospital had to be closed on account of the greatly reduced incidence of tuberculosis in this country. The High Wood experience was summarized in the book *Tuberculosis in Childhood and Adolescence*, published in 1954, and was further developed and evaluated in the many hundreds of carefully chosen slides which were deposited with commentaries in the Harveian Library of the Royal College of Physicians of London.

An asthmatic childhood and continued ill-health during his professional life imposed a great deal of restriction on him. In spite of this he was gregarious, liked good company, films, theatre, good books, and enjoyed good food. He was an erudite and witty conversationalist. He pursued many hobbies. Earlier on he was a keen gardener. Later, when ill-health kept him out of the country during the winter months, he became a passionate traveller and exquisite colour photographer. After his enforced retirement he became an excellent croquet player—defying his medical advisers—and died at Hurlingham, which he had come to love so much, after a pleasant game.

News and Notes

EPIDEMIOLOGY

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of acute pneumonia and meningococcal infection in England and

Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.

Infectious Diseases

Areas where numbers of notifications were high in the latest two weeks for which figures are available.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 16 September (No. 37) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

MEDICAL NEWS

M.R.C. Social Medicine Research Unit

The address of the M.R.C. Social Medicine Research Unit under Professor J. N. Morris changed from the London Hospital to the London School of Hygiene and Tropical Medicine on 1 October. On that date Professor Morris took up the Chair of Public Health in the University of London and became Honorary Director of the unit.

The M.R.C. have stated that the unit will be continuing its investigations of the causes and prevention of heart disease, particularly coronary thrombosis, the working of health services, and of social and psychological factors in delinquency. It will also be participating in the school's programmes for the training of community doctors.

European Society for Paediatric Nephrology

The foundation meeting of the European Society for Paediatric Nephrology took place in Glasgow from 17 to 21 September. So far the Society consists of 43 members from 20 European countries. The founders are Dr. GAVIN C. ARNEIL (University of Glasgow) and Dr. HARMAN A. W. M. TIDDENS (Wilhelmina Children's Hospital, Utrecht, Netherlands). During the course of the three-day meeting thirty scientific papers were read and the foundation lecture was given by Professor HENRY L. BARNETT, of the Albert Einstein College of Medicine in New York. It is intended that annual general meetings will be held, and arrangements are in hand for the next meeting in Utrecht in 1968.

Queen Elizabeth Hospital for Children

The hundredth anniversary of the founding of the hospital was commemorated on 18 September by a service at the Parish Church, St. Peter's, Bethnal Green. Other celebrations included a dinner and a garden party, while there was also an exhibition of past and present work of the hospital. A small illustrated brochure to commemorate the centenary is available from the Hospital Secretary (price 5s.).

Vaccination Against Smallpox

A new edition of the Ministry of Health's *Memorandum on Vaccination Against Smallpox* has recently been published (H.M.S.O., price 1s. 6d.). Among the principal changes are the description of the new presentation of vaccine in plastic tubing; the inclusion of pregnancy and leukaemia among the contraindications to routine vaccination; and complete revision of the paragraphs on the inspection and recording of results.

Degree Course for Nurses

Starting in September 1968, St. Bartholomew's Hospital, London, in co-operation with the City University, will select four of its student nurses to combine their nurses' training with a social science degree.

Miss K. M. HALPIN, a governor of the hospital, said at a conference recently that experiments in such integrated courses had already been introduced in a few hospitals in this country, and had proved successful. The course was intended for students whose first intention was to become a nurse, but who also had the desire and academic ability to read for a degree.

Miss W. E. HECTOR, principal sister tutor at St. Bartholomew's Hospital, emphasized that the introduction of this course in no way lessened the value of student nurses taking the ordinary general training leading to enrolment as State-registered nurses. But the future pattern of nursing was changing, and there would be a need in the higher grades for nurses who essentially must know the clinical background of nursing but who must also have the knowledge and experience to take up administration and to interpret and formulate policy and deal with social relations at the highest levels in hospitals, central government, and at international level. It would be a four-year course, the first year of which would be spent in the nursing school, before beginning the honours degree at the City University. It was hoped in time to increase the number of places available for nurses who wished to do the course.

A second scheme, which it is hoped to start at the same time, will link the London Hospital and Queen Mary College, in the University of London. This course will also last four years, but will lead to a degree in economics instead of in social science.

Erwin Stengel Prize

Professor E. STENGEL retired from the chair of psychiatry at the University of Sheffield last month. To mark the contribution he has made to the teaching of psychiatry, his colleagues have inaugurated a prize of £120 in his name. This will be awarded every three years to the doctor who has submitted the best piece of research in any field related to clinical psychiatry and carried out during tenure of an appointment in the Sheffield region. Preference will be given to doctors who have qualified not more than eight years. Any doctor is eligible whether or not he is working in a psychiatric setting. A statement of the prize and list of subscribers was presented to Professor Stengel at a reception at the University Staff Club on 29 September by Dr. H. V. DRICKS, President of the Royal Medico-Psychological Association.

Postgraduate Travelling Fellowships

The Governing Body of the British Postgraduate Medical Federation invites applications from registered medical or dental practitioners for a limited number of postgraduate travelling fellowships. Further details may be found on page xxxv of this week's advertisement columns.

Fulbright Travel Grants, 1968-9

Under the provisions of the Fulbright programme travel grants are available to citizens of the United Kingdom and dependent territories to go to the United States for academic and education purposes, such as study, research, or lecturing. Awards are competitive and are made by the Board of Foreign Scholarships in Washington on the recommendation of the United States Educational Commission in the United Kingdom. Applications should be made as soon as possible and details of the awards can be obtained from the Commission at 71 South Audley Street, London W.1.

Lalor Foundation Research Grants

The Lalor Foundation is offering awards for 1968 for research in the field of reproductive physiology. Awards may be for a

few months or up to one year, and may range from \$1,300 to \$8,500. Preference will be given to younger members of academic staff. Details and forms of application can be obtained from the Lalor Foundation, 4400 Lancaster Pike, Wilmington, Delaware 19805, U.S.A. The closing date is 15 January 1968.

National Council on Alcoholism

At a meeting of the National Council on Alcoholism held on 28 September the following appointments were made: *president*, Dr. LINCOLN WILLIAMS; *vice-president*, LORD EVANS OF HUNGERSHALL; *chairman*, Dr. W. A. R. THOMSON.

People in the News

► Professor I. FRIEDMANN was admitted to membership of the Collegium Oto-Rhino-Laryngologicum Amicitiae Sacrum at a recent meeting of the Collegium in Chicago.

News in Brief

Royal Air Force Hospital, Wroughton, Wiltshire, has been renamed Princess Alexandra's Royal Air Force Hospital.

The Speech Therapists' Professional Association will in future be known as the Union of Speech Therapists.

Recent Publications

A Report on Day-Care Centres and Residential Units, by a subcommittee of the Multiple Sclerosis Society of Great Britain and Northern Ireland, includes a summary of a national survey to members of the Society. As a result of the survey the subcommittee has recommended the building of two prototype combined day-care centre and residential units to be undertaken by the Society in the first instance. Copies can be obtained (postage 4d.) on application to the Society, 10 Stratford Road, London W.8.

What to Do When Someone Dies, a booklet describing formalities and procedure in England and Wales. Differences that apply to Scotland are noted. There is an index. Consumers' Association, 14 Buckingham Street, London W.C.2, 10s.

Coming Events

Institution of Electronic and Radio Engineers.—Symposium, "Ultrasonics in Medicine and Biology," 11 October, 2.30 p.m., Middlesex Hospital Medical School, London W.1. Fee 10s. Tickets from the Institution, 8-9 Bedford Square, London W.C.1.

National Society for Clean Air.—Annual conference and exhibition, 17-20 October, Empress Hall, Blackpool.

Abortion Law Reform Association.—Annual public meeting, "Abortion Bill—Will It Work?" 21 October, 7 p.m., Kensington Central Public Library, Phillimore Walk, London W.8. The chairman will be LORD SOPER, and speakers include Professor GLANVILLE WILLIAMS, Mr. P. L. C. DIGGORY, and Dr. ELIOT SLATER. Admission is free.

Research Defence Society.—Stephen Paget memorial lecture, "Animals in Captivity," by Professor A. S. PARKES, F.R.S., 24 October, 5.30 p.m., Physiology Lecture Theatre, University College London, Gower Street, London W.C.1.

Charing Cross Hospital Medical School.—Inaugural address by LORD INMAN, Thursday, 26 October, 5 p.m., at Royal Commonwealth Society, London W.C.2.

Royal College of General Practitioners.—Study day on "Practice Organization," in collaboration with the Postgraduate Board of Medicine, Edinburgh University, 28 October, 9.30 a.m., Western General Hospital (lecture theatre), Edinburgh (note change from Hume Tower). Applications to Dr. CONSTANCE GIBBS, Livingstone House, 39 Cowgate, Edinburgh 1.

Newcastle Regional Hospital Board.—Conference on "Prescribing, Distribution, and Administration of Drugs in Hospital," 28 October, 10 a.m., Physics Auditorium, Newcastle upon Tyne University. Details from the Secretary to the Board, Benfield Road, Walker Gate, Newcastle upon Tyne 6.

B.M.A. Mid-Essex Division and Chelmsford Medical Society.—Symposium, "Disabilities in Middle-age," 28-29 October, Broomfield Hospital, Chelmsford. Details from Secretary, Medical Academic Unit, Chelmsford and Essex Hospital, Chelmsford, Essex.

Societies and Lectures

For attending lectures marked Ⓢ a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Friday, 6 October

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Mr. W. M. Capper: Surgery in the Region of the Ampulla of Vater. (2) 6.30 p.m., Mr. R. H. Franklin: Replacement and Reconstructive Operations of the Oesophagus.

Monday, 9 October

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. H. Baker: Biology of the Epidermis.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., combined staff consultation clinical meeting.
KINGSTON-UPON-THAMES MEDICAL CENTRE.—(1) 5.15 p.m., slide seminar by Dr. M. E. A. Powell: Lymph Nodes. (2) 6.30 p.m., Dr. G. B. Hill: Basic Statistics.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Professor J. C. Goligher: The Place

of Surgery in the Treatment of Ulcerative Colitis. (2) 6.30 p.m., Sir Clifford Naunton Morgan: Inflammatory Diseases of the Large Intestine.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. S. Shaldon: Intermittent Haemodialysis in the Home.

SOCIETY OF INSTRUMENT TECHNOLOGY.—At Royal Institution, 6 p.m., Thomson lecture by Sir Henry Jones: Sources and Uses of Energy.
WHIPPS CROSS HOSPITAL.—At Medical Education Centre, 8.45 p.m., Leyton Doctor-Clergy Group meeting.

Tuesday, 10 October

B.B.C. 2 TELEVISION.—1.15 p.m., medicine today: Rheumatoid Arthritis. (Sponsored by A.S.M.E.)
HEATHERWOOD HOSPITAL, ASCOT.—At Outpatient Hall, 8.45 p.m., Mr. J. G. Taylor: The Painful Shoulder—Differential Diagnosis.
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Professor C. D. Calnan: Pattern of Cutaneous Disease.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 2 p.m., Professor D. V. Fairweather: Perinatal Mortality. (Admission by ticket only, obtainable from Secretary, Institute of Obstetrics and Gynaecology, Chelsea Hospital for Women, London S.W.3.)
KENT AND SUSSEX HOSPITAL.—8.30 p.m., Professor W. H. Trethowan: The Couvade Syndrome.
NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., Mr. J. E. Mitchell: Minor Ano-Rectal Conditions.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Mr. D. R. Davies: Surgery of the Parathyroid Glands. (2) 6.30 p.m., Mr. K. Bloor: Principles of Treatment of Peripheral Vascular Occlusion.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Professor R. Shackman: Uraemia.
WHIPPS CROSS HOSPITAL.—At Medical Education Centre, (1) 1.15 p.m., B.B.C. programme, medicine today: Rheumatoid Arthritis; (2) 5 p.m., seminar by Dr. P. Marshall Jones: Renal Function Tests.

Wednesday, 11 October

BRITISH SOCIETY FOR THE HISTORY OF PHARMACY.—At Pharmaceutical Society of Great Britain, London W.C., 7 p.m., Dr. Marie B. Hall: Apothecaries and Chemists in the 17th Century.
CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. Y. M. Clayton: Identification of Pathogenic Fungi.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. R. L. Yeager (New York): A Combined Hospital and Outpatient Programme for the Treatment and Control of Tuberculosis.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Society of Medicine, 8.30 p.m., symposium: Medical Problems of the Immigrant.
MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Theatre, Manchester University Medical School, 5 p.m., Dr. A. Goldberg: Iron and Anaemia.
ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5.30 p.m., postgraduate museum demonstration by Mr. C. J. Mackinlay: Ovarian Tumours.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Mr. D. Ranger: Tracheostomy and Endotracheal Intubation. (2) 6.30 p.m., Dr. A. R. Harrison: Calcium Metabolism and the Kidney in relation to the Formation of Calculi.

ROYAL FREE HOSPITAL.—5.15 p.m., Dr. G. P. McNicol: Fibrinolysis.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conference by Dr. C. T. Dollery, Dr. E. D. Williams: Hyperaldosteronism. (2) 2 p.m., Dr. G. A. Rose: Calcium Metabolism in Relation to Metabolic Bone Disease.

STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Mr. R. R. L. Pryer: clinical cases. (2) 6 p.m., Dr. C. S. Pitcher: Megaloblastic Anaemias—II.
WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Dr. M. W. McNicol: Management of Respiratory Failure.

WHIPPS CROSS HOSPITAL.—At Medical Education Centre, course for general practitioners, 2 p.m., Dr. N. Galbraith: Immunization and Immunology; 3 p.m., Dr. H. Wyatt: Physical Medicine in Hospital and Community.

Thursday, 12 October

DUNDEE UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Sir Edward Wayne: The Impact of Automation on Clinical Medicine.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.15 p.m., presidential address by Mr. M. Klein: Glaucoma.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5 p.m., Gordon-Watson lecture by Brigadier J. M. Matheson: Infection in Missile Wounds. (2) 6.15 p.m., Mr. A. H. Hunt: Management of Portal Hypertension and its Complications.
ROYAL NORTHERN HOSPITAL, London.—5 p.m., Professor F. T. G. Frunty, Dr. J. Jenkins, Dr. C. W. H. Havard: Hirsuties.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. J. A. H. Hancock: Reiter's Syndrome.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Mr. D. J. MacRae: The Acid Base Relationship between the Mother and the Foetus.

Friday, 13 October

BRITISH GERIATRICS SOCIETY.—At Royal College of Physicians of London, 5.30 p.m., Guinness lecture by Professor G. Bull: Myocardial and Cerebral Infarction.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 3 p.m., discussion: Endometriosis. Speakers, Mr. D. W. T. Roberts, Mr. W. L. Whitehouse. (Admission by ticket only, obtainable from Secretary, Institute of Obstetrics and Gynaecology, Chelsea Hospital for Women, London S.W.3.)
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Mr. J. L. Hayward: An Assessment of Etiological Factors in Breast Cancer in relation to Treatment. (2) 6.30 p.m., Mr. M. A. Falconer: Surgery in Lesions of some of the Cranial Nerves.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 10.15 a.m., Dr. L. M. Franks: Hormonal Control of Normal and Malignant Tissues. (2) 11.30 a.m., Professor R. Shackman: clinicopathological conference (urology). (3) 4 p.m., Dr. J. W. Laws: Radiology of the Small Intestine.
WHIPPS CROSS HOSPITAL.—At Medical Education Centre, (1) 11.30 a.m., child psychiatric case conference by Dr. W. R. Little; (2) 1 p.m., medical films and discussion.

Saturday, 14 October

ROYAL POSTGRADUATE MEDICAL SCHOOL.—9.30 a.m., anaesthetic teaching meeting: Humidification and Intermittent Positive Pressure Ventilation.

Deaths

Cox.—On 27 September 1967, at 2 Oaks Road, Church Stretton, Shropshire, George Lissant Cox, C.B.E., M.D., aged 88.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitology*, London W.C.1. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

ABSTRACTS OF WORLD MEDICINE

The September issue (Volume 41, No. 9) contains in addition to abstracts of papers from current world medical literature a review article entitled:

Automation—Another Change in Working Environment
By P. A. B. Raffle, M.D., M.R.C.P., D.P.H., D.I.H.

This article examines the ways in which automation may improve or impair the well-being of men and women transferred to it and how the biological and social sciences can contribute to reducing the impact of the change.

Published monthly. Yearly subscription £6 6s., U.S.A. \$18. Single issue 12s. 6d.

MEDICAL AND BIOLOGICAL ILLUSTRATION SPECIAL SCHOOLS SYMPOSIUM

The Role of a Developmental Paediatric Centre. Ronald Mac Keith.
That the Delicate Child Shall Take His Proper Place in Society. Florence M. Burnet.
A School for Maladjusted Deaf Children. Cyril E. Williams.
Lingfield Hospital School for Children with Epilepsy. James C. Bowe.
A Day School for Physically Handicapped Children. Stanley S. Segal.
Educating the Blind Child. M. S. Colbourne Brown and Ann Reid.
A New Approach to the Education of Partially Deaf Children. A. B. Thomson.
The Handicapped Child at Home. Elizabeth Campbell.
Gardening for the Disabled Child. A. S. White.
Some Recent Contributions to the Study and Welfare of Handicapped Children. Elisabeth C. W. James, James Lumsden, and T. A. Quilliam.

Pointers

Penicillinase: Bacterial enzymes that destroy penicillins are discussed by Professor M. R. Pollock, who considers they may have had a common evolutionary origin and may be of importance in nature (p. 71). *Leader*, p. 66.

Hepatic Coma: Drs. J. A. McLean and H. A. Luke, of Melbourne, describe four patients with hepatic coma, with one recovery, who were treated by exchange blood transfusion (p. 78).

Influenza: Dr. Marguerite S. Pereira and colleagues report that an epidemic due to current strains of virus is unlikely (p. 80). Dr. G. C. Schild and Professor C. H. Stuart-Harris discuss the possibility of foretelling influenza outbreaks from information about antibodies in children (p. 82). *Leader*, p. 67.

Blood Loss: Dr. J. M. Holt and colleagues describe a sensitive method of measuring blood loss with radioactive iron (p. 86).

Blood Rouleaux: Some plasma expanders but not others cause rouleaux to form and may interfere with blood grouping, according to Dr. A. J. Salisbury (p. 88).

Paget's Disease: Six cases in three generations are reported by Drs. J. Verrier Jones and Mervyn F. Reed (p. 90).

Autonomic Nerves: In a familial form of autonomic nervous disease the pupil responses are described by Dr. E. Shinebourne and colleagues (p. 91).

Postoperative Gas Gangrene: A leader discusses why thigh amputations for obliterative arterial disease are specially hazardous (p. 68).

C.M.O.'s Report: Sir George Godber is critical of "firm" system in hospitals (p. 69).

Case Reports: Corrosion of stomach simulating carcinoma (p. 93); complications of methyl-dopa (p. 94); Goodpasture's syndrome (p. 95); ichthyosis and breast cancer (p. 96).

Digestive System: In "Current Practice" Dr. N. F. Coghill discusses the diagnostic significance of dyspepsia (p. 97).

"Medicine Today": An article on the management of rheumatoid arthritis complements the television programme on the subject (p. 99).

Human Experimentation: C.I.O.M.S. conference on ethics (p. 105).

Aspirin and Gastric Bleeding: Correspondents question whether paracetamol is the right alternative (p. 107).

Safer Night Driving: Article by Motoring Correspondent (p. 119).

Scottish Hospitals: Meetings of Scottish Committee for Hospital Medical Services and Hospital Junior Staffs Group Council (*Supplement*, pp. 11 and 13).

B.M.A. Planning Unit: Progress report (*Supplement*, p. 14).

Postgraduate Education in Scotland

In September 1965 the Scottish Postgraduate Medical Association, on the invitation of the Scottish Home and Health Department, set up a working party "To inquire into the needs of postgraduate medical education in Scotland so far as the National Health Service is concerned." The report¹ has now appeared, and though approved by the association in principle for wider circulation it is not put out as a statement of agreed policy. The outcome of considerable, though uncoordinated, activity in postgraduate education in Scotland, discussed also at a conference held in Glasgow earlier this year,² the report owes much to the stimulus given to this whole problem by the Nuffield Provincial Hospitals Trust in 1961. What has emerged is that education and training must go hand in hand and that "they must be placed upon a more organized footing than was thought necessary in the past."

The report outlines the role of the universities in providing teachers, libraries, laboratories, and so on and in the supervision of the preregistration year; of the colleges in setting professional standards, offering specialist courses, and holding examinations; of the N.H.S. in providing the training posts, supervision by senior staff, study leave, secondments, and facilities for research; and of the Postgraduate Association in bringing together the various bodies concerned. However, despite certain advantages in Scotland there seems to be a lack of co-ordination, and no central authority can be identified as ultimately responsible for carrying out a policy, properly conceived and financed.

If postgraduate training in an era of intense specialization is to be effective it must be continuous from the undergraduate period until retirement, as was likewise stressed in the report on medical education submitted last year by the British Medical Association to the General Medical Council.³ Consequently the discontinuous career structure in the Health Service should be revised to enable junior staff to undertake planned schedules of training leading to their chosen vocation, thus bringing them into line with senior registrars. The report looks forward to a five-year period of basic medical education followed by two years' preregistration, in the second year of which some specialization might be begun. Thereafter at S.H.O.-registrar level there should be a regionally organized and financed system of in-service specialist training, with rotation through teaching and district hospitals and laboratories. To carry out a scheme of this kind would require a central postgraduate organization with associated regional and area bodies. This organization would bring together representatives of the National Health Service, the universities, and the colleges, but it would be expected that the main financial burden would fall on the National Health Service.

Special concern was expressed for the training of general practitioners. It is recommended that the training should extend over four years, that two years should be spent in hospital and two in teaching health centres. The need to develop comprehensive health centres is strongly argued.

The competing claims of staffing for service needs and for training are considered in some detail, particularly in the appendix on surgery. Since only a fraction of S.H.O.s and registrars in any specialty will eventually become consultants in that specialty, alternative careers must be offered. In the case of surgery, for example, it is suggested that about half the registrar posts should be earmarked for the training of future consultant surgeons in the N.H.S. This would maintain a ratio of registrars to senior registrars of about 5:4. The remaining surgical posts would be filled by Commonwealth trainees and trainees for general practice. This pattern is worthy of serious consideration.

The report is both realistic and practical. It deals largely with existing institutes, facilities, manpower, and staffing structure, and it suggests how we may make the best

use of what we now have. For this reason the role of the teaching hospital is given most prominence and that of community medicine the least. The stimulus it offers to new developments in patterns of patient care is welcome. It expects that, before long, registration of specialists (which would include general practitioners) will be introduced as outlined in the 1967 Recommendations of the G.M.C.⁴ and suggests that active steps should be taken now to bring this about.

Origin of Penicillinase

Penicillins are attacked by two enzymes of microbic origin. One is amidase, which simply severs the side-chain leaving the nucleus intact, a reaction which is now the first step in producing the many new semisynthetic penicillins. The second is penicillinase, which opens the β -lactam ring of penicillin and deprives it of all antibacterial activity. It was recognized more than 20 years ago that this enzyme was formed by some strains of staphylococci, and that they owed to this their resistance to the antibiotic. These strains have little "intrinsic" resistance; it is not that they can tolerate penicillin, but that they can destroy it. All resistance to penicillin in staphylococci is of this nature. The formation of this enzyme at a site of infection can prevent the action of penicillin on another fully sensitive organism. Thus in mixed infections by staphylococci and haemolytic streptococci treatment with cloxacillin may be indicated, since it is both resistant to penicillinase and active against the streptococcus.

Soon after the recognition of staphylococcal penicillinase it was found that other bacteria form the same kind of enzyme. These include many Gram-negative bacilli such as species of *Pseudomonas*, *Proteus*, and *Klebsiella*, various *Bacilli* such as *B. cereus* and the anthrax bacillus, and even tubercle bacilli. In some of these organisms resistance to penicillin does not depend entirely or even largely on the enzyme; many of them also possess a high degree of intrinsic resistance. An exception is *B. anthracis*, which is intrinsically so sensitive that anthrax responds readily to treatment with penicillin. The structure of penicillinases—and cephalosporinases, corresponding enzymes attacking the nucleus of the cephalosporin group of antibiotics—is not exactly known, but it is clear that they are a family of enzymes and not a single substance. Many of these enzymes are inducible—that is to say, exposure to a penicillin will immediately cause them to be formed in much larger amount. It has also been established that different penicillins vary in their capacity to act as inducers, and indeed nafcillin is claimed to have a therapeutic advantage in that it is a very weak inducer of penicillinase formation.

Professor M. R. Pollock, who has made extensive studies of penicillinases and the kinetics of their formation and activity, chose this subject for an Almroth Wright lecture

which we print on page 71. His title refers to the origin and function of penicillinase as a "problem in biochemical evolution," and the main question which he asks is how it came about that some bacteria form such an enzyme, which is of no use to the cell forming it except as a means of eliminating an antibiotic from the environment. He reaches the interesting conclusion that formation of the enzyme may have resulted from an evolutionary change related to this very function. Some of his arguments will be appreciated only by those with a considerable knowledge of bacterial chemistry, but others will make a more general appeal. He points out, for instance, that the distribution of numerous moulds now known to form penicillin and of bacteria forming penicillinases is not dissimilar. Their habitats include not only the soil but the skin, where an interesting example is the reported coexistence of a penicillin-forming dermatophyte and a penicillinase-forming staphylococcus on the skin of hedgehogs. Two other pieces of evidence are derived from hitherto unpublished work. It has at last been shown that a *Penicillium* will actually produce penicillin in natural soil in the laboratory. Secondly, Pollock himself has shown in the same environment an antagonism between the growth of a penicillin-forming mould (*P. chrysogenum*) and a penicillinase-forming bacillus (*B. licheniformis*) in the sense that when growing together they attain lower total numbers than either growing alone.

This tentative conclusion has wider implications. Soil has been searched for antibiotic-forming species on a gigantic scale not only because it contains an enormous variety of micro-organisms but because it was originally regarded as a battle-ground of warring species, their weapons being antibiotics. Of late years this belief has lost many adherents, and antibiotics are commonly regarded as having no natural function—at least of any importance. In the words of S. A. Waksman and H. A. Lechevalier,¹ "... we can conclude that the production of antibiotics, as we visualize it in the laboratory, does not occur in nature ... too little solidly grounded information is available to warrant much more than speculation about the ecological significance of antibiotic production." If we are now to grant that penicillinase formation is the result of an evolutionary process of a

¹ Waksman, S. A., and Lechevalier, H. A., *The Actinomycetes*, 1962, vol. iii. London.

defensive nature, it follows that antibiotics themselves have a function in suppressing other species than those forming them and thus securing a more liberal supply of nutrient. "Nature red in tooth and claw," an expression intended to refer only to the animal kingdom, has thus an equivalent even among the lowest plants—a forbidding thought to the believer in peaceful co-existence as a natural way of life.

Spread of Influenza

The prognosis of an individual patient's disease is always difficult even with a straightforward infection like influenza. Likewise to predict the appearance and course of epidemics is chancy. Nevertheless international co-operation, particularly through the World Health Organization's Reference Centres, has given us a fairly complete picture of what is happening to the viruses causing influenza epidemics.

In 1947 and in 1957 completely new serotypes of influenza appeared—types A1 and A2—and these spread across the world, producing large epidemics. More epidemics followed in later years, and comparison shows that the virus strains have changed the antigens on their coats appreciably. This is presumably because new variants have a better chance of survival against the antibody induced by the last variety of influenza. Two distinct new antigenic modifications have occurred since the first A2 (Asian 'flu) viruses appeared, and have usually been associated with new epidemics.¹⁻⁶

However, whether a virus spreads in a country depends not only on the "newness" or otherwise of its antigens but on the antibodies the inhabitants are carrying. Influenza A in Britain tends to recur at about two-year intervals,⁷ but recent years have shown exceptions to this rule (which is not followed in other parts of the world). It has therefore been suggested that if we know the immune status of the population of a country, in particular if we know the number of people carrying antibody against the current strain, then we may be able to predict an epidemic, and perhaps forestall it by vaccinating with the virus for which the population has no antibody. When new strains have appeared such studies have been made, and they are easy to interpret. In the 1957 pandemic only the very old had antibody against the A2 virus strain, and everyone else had no antibody and was susceptible. In the interpandemic period serological surveys are not so easy. Such studies have been made abroad, usually with the haemagglutination-inhibition tests to detect the antibody.⁸ The first of such studies from Great Britain are reported in this issue of the *B.M.J.* (p. 80). Dr. Marguerite Pereira and her colleagues report that sera were collected from October 1965 to May 1966 from routine blood specimens examined in public health laboratories, and were tested by a specific complement-fixation test for antibodies against the surface (V) antigens of recently isolated strains of influenza A2 and B. Only about one-half of the preschool children had antibody against influenza A and a quarter against influenza B, but over half the school-age children and adults had antibody. The peak level of antibody to recent strains was in the age group 15–24, possibly because they had been heavily affected by influenza and also because they had relatively little experience of the antigens of the earlier influenza serotypes which "condition" the immune mechanism to produce antibody against the earlier types rather than against the recent ones. This phenomenon was

called "original antigenic sin,"⁹ and the mechanism has recently been studied by reproducing the phenomenon in rabbits injected successively with different influenza virus vaccines.¹⁰ It is thought to occur when clones of antibody-producing cells proliferate after the first antigenic experience of the virus, and are restimulated when partly cross-reacting antigens are met. But if large amounts of such new antigens are given they may not be adequately dealt with and may stimulate the formation of a new clone.

The second study, by Dr. G. C. Schild and Professor C. H. Stuart-Harris, appears at page 82. They used sera collected from children in South Yorkshire in three periods—namely in 1965, early 1966, and the winter of 1966–7. There was an outbreak of influenza due to both A2 and B viruses in the area in 1966, and the study therefore sheds light on the response of the "antigenically inexperienced" part of the population. In general antibody was less common and of lower titre in the younger children. Though most children had antibody against the 1964 influenza A2 before the epidemic, there was by 1966 a marked increase in the number with high titres, presumably as a result of natural exposure. Fewer children had antibodies against the 1965 influenza B strain, but the proportion of these with medium or low titres increased during the epidemic. The lowest frequency of antibodies was found in each case against the most recently isolated strain of influenza—that is, the 1966 strain—though by tests with sera prepared in the laboratory their antigenic composition did not seem to be particularly different from the viruses isolated one or two years before. The authors suggest, in fact, that tests with children's sera may be the most delicate way of distinguishing between closely related influenza viruses, and certainly differences shown with human sera may well be important in epidemiology. On the other hand, sera from adults would probably distinguish between viruses less sharply than animal sera do.

The results of the survey by Dr. Pereira and her colleagues show that many people have antibody against the current influenza virus strains, and the authors say we are unlikely to have an epidemic due to these or similar strains. This is reassuring, but it leaves another question unanswered. How

long will it be before the virus changes sufficiently to evade the immune barrier which the human herd has raised against it?

Attempts to produce the "next" variant in laboratory animals have not been successful.¹¹ In recent years it has become clear that influenza A and B viruses can in fact be isolated from cases of respiratory disease between epidemics, in periods when clinical or epidemiological observations such as the frequency of deaths from pneumonia, sickness claims, or outbreaks in institutions or local communities do not show that an epidemic is in progress. Thus, though the virus may seem to have disappeared, it can be found if looked for sufficiently thoroughly. However, so far no new serotype has been caught in the act of antigenic evolution.

An even less predictable event is the appearance of radically new influenza viruses, such as the Asian influenza virus. For many years it was thought that they might come from an animal reservoir. Unfortunately, in the best-studied example, that of influenza in American pigs, it seemed more likely that the virus had gone from man to pig in the 1918 epidemic rather than the reverse. But it does now provide a good example of an influenza virus which maintains itself in animals. Its life cycle, involving earthworms and nematodes, is rather extraordinary, but it is apparently independent of man—except that it is man who keeps the pigs. However, in recent years we have learnt much more about influenza viruses in animals. It was discovered in 1955 that the long-known fowl plague virus is actually an influenza A virus,¹² and since then there are also other antigenically distinct influenza A viruses affecting ducks,¹³ turkeys, terns, and game birds, and two different serotypes have been recovered from horses both in Europe¹⁴ and in North America.¹⁵ Human beings have been infected experimentally with one of the horse viruses, but large doses were used and only one volunteer became sick.¹⁶

Antibody against one of the horse viruses has been found in the sera of old persons.^{17 18} It is difficult to interpret this. But if man was infected in the last century with a virus related to one now infecting horses, that does not prove that it came from horses or from any other animal. Furthermore, there is no well-documented instance of an epidemic beginning in animals and spreading to man, though it might be a rare event and also take place in economically impoverished places where man and animals live close together and opportunities for precise observation are few. There are examples of almost completely new antigenic serotypes of influenza B which produced local outbreaks of disease in man but did not spread across continents as they were expected to do.^{19 20} They apparently lacked something, perhaps the ability to survive in air and so spread rapidly, which would have made them into completely successful epidemic strains. So animal influenza viruses which would ordinarily grow rather poorly in the cells of man would, if the theory were correct, be likely to produce a few cases more often than a distinct epidemic. Any possible examples should be quickly reported and investigated by expert virologists.

Recent experiments on mice^{21 22} have shown that the virus is transmitted as airborne droplets, and that the rate of transmission can be reduced by increasing ventilation and modified by the temperature and humidity of the air. Some viruses are much better "spreaders" than others, though it is still not clear why they are. Further experiments, just described,²³ show that though serious disease can be prevented by vaccinating mice with live or killed vaccine the live vaccine also reduces the ability to transmit infection to other animals

when mice are reinfected, while mice protected with killed vaccine can still act as transmitters.

The epidemiology of influenza is rather like the study of economics: it does not tell us what is going to happen so much as why things happen after they have done so. Consequently a prediction for the coming winter in Britain must be based on a balance of probabilities. Two years ago we had influenza A2 and B, so we might expect influenza A2 to return this year, as it seems to have done in the southern hemisphere during our summer. There is no sign of a radically new antigenic type of virus, and many people carry antibodies against the current types. So if an epidemic comes it is likely to be mild.

Postoperative Gas Gangrene

It has recently been reported in the daily press that two cases of gas gangrene, one of them fatal, have followed amputation through the thigh in a Birmingham hospital, and that an operating-theatre suite has consequently been closed. Some comments on this occurrence¹ refer to the ubiquity of pathogenic bacteria in the hospital environment and the necessity for greater and very expensive precautions in order to reduce the risk so entailed. A further report² concerns three cases of gas gangrene at a London hospital, but gives no information about the circumstances in which they arose.

No lessons can be drawn from these two episodes until a full account of them is available, but there are certain facts about the causation of this infection, and particularly with regard to its source, which apparently deserve to be more widely known. The organism almost invariably causing postoperative gas gangrene is *Clostridium welchii*. It is a normal inhabitant of the bowel of man and animals, and almost always to be found in soil, dirt, and dust. Its spores are capable of prolonged survival. Their exclusion from the hospital environment is impossible. For instance, E. J. L. Lowbury and H. A. Lilly³ found them in every sample of air examined in a hospital, including that of operating-theatres. Moreover, the organism is not uncommonly present in the exudate from traumatic wounds or burns which are the seat of nothing more than transient suppuration. It is thus implanted in many traumatic wounds and probably in a substantial proportion of surgical wounds without giving rise to the acute necrotising myositis with formation of gas which is gas gangrene.

What, then, is the missing factor which ensures these patients' safety? It is simply that the tissues involved have an adequate blood supply and thus an oxygen tension in which clostridia cannot grow. The spores of an anaerobe cannot even germinate in a tissue normally supplied with blood. In traumatic gas gangrene the infection originates in muscle which has been crushed or cut off from its blood supply. Only profuse growth of clostridia in such an area can create conditions in which normal muscle can subsequently be invaded.

For three reasons gas gangrene is more likely to follow thigh amputation for obliterative arterial disease than other

operations. Firstly, the incision must be through skin not far distant from the anus, and intestinal bacteria are more widely distributed over this area than is commonly realized; among them the spores of clostridia are resistant to ordinary methods of skin disinfection. Secondly, the operation entails severing large masses of muscle in which bacteria from the region of the incision can be directly implanted. Thirdly, and most important, the disease which has necessitated the operation reduces the blood supply to the area, and may thus reduce the oxygen tension to a level permitting clostridial growth. The degree to which this area is so affected is doubtless one variable factor determining the outcome. Others are the efficacy of skin cleansing and the toxigenicity of the patient's own strain of *Cl. welchii*. This is a property in which different strains vary widely.

This operation carries the imperative indication for penicillin cover in doses allowing for the fact that clostridia are less sensitive to penicillin than, for instance, streptococci. At least 500,000 units should be given at intervals of not more than six hours for seven days.⁴ Other operations with a similar risk meriting penicillin cover were recently referred to in our correspondence columns by M. J. Parker.⁵

Gas gangrene is a rare and terrifying condition, and it is perhaps natural that operating-theatre staffs should regard it as calling for exceptional measures. In fact it is much easier to disinfect a theatre after a case of gas gangrene than after a dirty operation on the lower bowel, because in the former the organisms are all in the vulnerable vegetative form, whereas in faeces they exist largely as resistant spores. That most strains from the normal bowel are as toxigenic as those which have had the opportunity of causing gas gangrene has been shown by D. J. E. Price and R. A. Shooter.⁶ It remains to be seen whether conditions in the operating-theatres concerned in these recent episodes are considered to require improvement. What can be said with some confidence is that when gas gangrene follows thigh amputation there is no need to look any further for the source of infection than the patient's anus.

Standardization in Human Cytogenetics

The explosion in our knowledge of human chromosomes and their abnormalities which has occurred during the past ten years has resulted in many difficulties, particularly of communication and nomenclature. There have now been three conferences to consider these problems. The first of these was in Denver in 1960, the second in London in 1963, while the third and last was convened at the University of Chicago in September 1966. The aim of each of these meetings has been to improve communication and understanding in the field of human cytogenetics. At Denver order was brought into the system of numbering human chromosomes, and the international system agreed at that meeting has remained essentially unaltered since. In London the Denver system was consolidated and the alternative use of letters to classify the different chromosome groups, which had been advocated by some workers since 1961, was agreed internationally to be a useful alternative to the Denver system of nomenclature. At the conference it became clear that little progress had been

made in chromosome identification over the three preceding years.

The report of the Chicago Conference, published recently, is perhaps one of the most important documents published in the field of human cytogenetics. It considers new means for describing the normal chromosomes and deviations from the normal complement, and proposes an entirely new system of notation for the uniform description of the human chromosome set and its abnormalities. This shorthand system is also applicable to the description of the somatic chromosomes of non-human species, so that perhaps from this conference a universal system of notation may eventually develop. The system is most carefully designed so that it should be adaptable to automated data processing and information retrieval systems, which are becoming more and more widely used.

Other topics discussed at the meeting included the recording of data, and recommendations are made in the report on the essential information required if accounts of chromosome abnormalities and variation are to have maximum value. The place of autoradiography in chromosome identification was considered as well as problems related to the automation of chromosome analysis, population cytogenetics—and in particular the types of population suitable for study and the information which might be derived from such studies—and the effects of radiation and mutagenic substances on chromosomes.

The conference needs following up in two important respects. Its recommendation "that in view of the expansion in human cytogenetics during the past six years it is now desirable to explore the feasibility of establishing a central organization for collecting and analysing data on the variability of the human karyotype" should be acted on by the appropriate international and national bodies. Secondly, its report is available. If investigations and journals publishing paper in this and related fields would use the system of notation recommended in the report then the clarity of published work would be considerably improved. In the past there has been confusion, and valuable data have been lost by the publication of inadequate and incomplete case reports. Widespread acceptance of the recommendations of the Chicago conference should make this a thing of the past.

Health Priorities

The Ministry of Health's team visiting the U.S.A. and Canada to persuade British medical emigrants to return is now at work. Can it offer the attraction that conditions are so different from what they were, or what the emigrants thought they were, that some will be tempted to return? The Ministry's views, as expressed by its Chief Medical Officer, Sir George Godber, in his annual report,¹ are robustly hopeful of better times ahead for doctors working in both hospital and general practice. That the department has its views also on what the profession should be doing is apparent from Sir George's observation that, "Given an acceptable and workable opportunity . . . the medical profession has shown its ability to work constructively and successfully with the department."

In his introduction Sir George dwells on the year he is reviewing, 1966, as one that "may well be seen in retrospect

¹ *Chicago Conference: Standardization in Human Cytogenetics*, Birth Defects, Original Article Series, 1966, Vol. 2, No. 2, New York. Copies can be obtained free from the Medical Department, The National Foundation—March of Dimes, 800 Second Avenue, New York, N.Y. 10017.

is the critical year" for new developments in the Health Service and also as "a turning point." The new arrangements in general practice came into being and do indeed offer a better framework in which to practise medicine. But among the outstanding problems remaining are the closer co-ordination of the different branches of medical practice and improvement in the opportunities for postgraduate and continuing education. The justifiable complaint is still prevalent among registrars that training for a consultant career is overwhelmed by the provision of care of patients. Sir George criticizes the arrangement of hospital staffs in "firms" as tending to preserve "the wasteful, inalienable ownership of hospital beds by individual consultants." He complains that last year's report on management functions of hospital doctors produced by the Advisory Committee on Management Efficiency² seems to have had less attention than it deserved—but this may be because it did not inspire the confidence of some of the readers to whom it was directed. The general pattern that Sir George outlines is of large district hospitals ("we are still struggling with several times as many hospitals as we need") linked with groups of general practitioners, mainly in health centres, working in close partnership with hospital specialists. In an increasingly urban population such arrangements seem likely to be a natural development.

Though Sir George reports that "Broadly the health record of the year was favourable," it is evident from a later section of the report that Britain's health is not all it should be. Despite the risks of drawing conclusions from international comparisons of statistics it is impossible to dismiss as of no consequence Britain's relatively poor showing in this respect. The Ministry has ranked a number of developed countries by standardized death rate, late foetal death rate (stillbirths), infant mortality rate, and maternal mortality rate combined. In this list the United Kingdom comes eighth, bracketed with the U.S.A., despite its very different arrangements for medical care. Countries with better health statistics are, in order of ranking, Sweden, Switzerland, Australia, Netherlands, Canada, Czechoslovakia, and Belgium. Though such facilities as the health services of these countries provide are only part of the explanation for their ranking in the league table, any judgement on the N.H.S. must take account of the U.K.'s relatively low position. Are its priorities right? is a question that has been asked before.

Wandering Oesophagus

Displacement and deformity of the oesophagus as found on barium-swallow examination provides a valuable aid to the diagnosis of many intrathoracic lesions. In most cases the changes are constant and do not vary during a single examination or even during successive examinations, but N. Shahin¹ has recently drawn attention to the fact that in cases of displacement of the lower third of the oesophagus considerable alteration in its position can occur. He describes this finding as "wandering oesophagus," a term which appears

to have been first used by E. Zdansky.² J. F. K. Hutton³ used the same term to describe a changing displacement of the lower third of the oesophagus in a case of mitral stenosis with enlarged left auricle. In his case he found that at one time the displaced oesophagus was pushed backwards and to the right (the usual displacement), while at a later stage in the examination, after a change in the patient's posture, the oesophagus slid over to the left. M. Brombart in his comprehensive monograph on the oesophagus⁴ describes a similar case, and it is of interest that his patient complained of considerable pain when the oesophagus was displaced to the right but was quite free of pain when it lay to the left of the dorsal spine. Shahin found 12 examples of wandering oesophagus during a single year, and he suggests that the condition is more common than is generally realized and would be found more frequently if radiologists looked carefully for it.

The thoracic aorta commonly becomes dilated and tortuous with advancing age, especially in the presence of hypertension. These changes produce a characteristic displacement of the lower third of the oesophagus, which often shows mild compression, as described by P. G. Keates and O. Magidson.⁵ The changes in position do not usually cause pain and only rarely are they associated with obstructive symptoms. The experience of Shahin and Brombart suggests that wandering of the oesophagus may well explain some of the cases of intermittent pain of oesophageal type, usually associated with dilatation and tortuosity of the aorta, but occasionally in association with mitral valve disease. In such circumstances it would be worth while subjecting the patient to the manœuvres described by Shahin to see if the displaced oesophagus changes position and to note if this change is associated with the pain. Shahin found that repeated acts of swallowing while the patient lay prone or while leaning forward were most likely to induce the oesophagus to wander.

International Relations

To foster contact between members of the medical profession throughout the world the Royal Society of Medicine has set up an Office for International Relations in Medicine. Supporting the venture are the Royal Colleges in England and Scotland. The first director of the office is Dr. Hugh Clegg, and perhaps a specially warm welcome for the choice may be allowed in this journal, for which during his 20 years of editorship he did so much to build up an international reputation. Nobody can doubt the need for such an office at present. The world of learning seems to contract the faster it goes, according to some relativity principle yet to be formulated. News by satellite and travel by jet have made neighbours of all mankind. Nowhere is this truer than in medicine.

The basis of the new office is to be a register of relations between British medical schools, medical institutions, and specialist medical societies with similar bodies and medical centres in other countries, particularly in the Commonwealth. Medical centres as well as individuals should find the register useful, and in helping to ease medical communication throughout the world it will be complementing the work of the Commonwealth and International Medical Advisory Bureaux run by the B.M.A., which are able to offer much help and advice to individual visitors. The address of the R.S.M.'s Office for International Relations in Medicine is Chandos House, 2 Queen Anne Street, London W.1.

Papers and Originals

Origin and Function of Penicillinase: a Problem in Biochemical Evolution*

M. R. POLLOCK,† M.B., F.R.S.

Brit. med. J., 1967, 4, 71-77

The title of this lecture is intentionally provocative. It is well known that there are many varieties of the enzyme that can split the β -lactam bond of penicillins and/or cephalosporins (Fig. 1)—the specific reaction referred to generally as “penicillinase.” And their physiological role in the life history of the bacteria which produce them is still a matter of controversy. But the case I wish to argue will be one in favour both of recognizing the relation between the various “brands” of the enzyme, despite many striking chemical differences, and of considering the possibility of a common or similar evolutionary origin.

FIG. 1.—Basic structure of penicillins and cephalosporins, showing the position of the main variant side-chains (R_1 , R_2) and the specific β -lactam (CO-N) bond (indicated by the oblique double line) that is split by “penicillinase.”

At our present state of knowledge the history of penicillinase began in 1689. I know there was no enzymology in those days, but I'll explain how a little later on.

The penicillin and cephalosporin β -lactamases are produced by a wide range of Gram-positive and Gram-negative species of bacteria, and differ from each other enormously in the relative rates at which they hydrolyse different substrates. The range of substrates, which differ (in the penicillin class) in the side-chain (R_1) attached to the free NH_2 group of the “nucleus,” 6-amino-penicillanic acid, and (in the cephalosporin class) in that side-chain and also in the side-chain (R_2) attached to C_3 of the cephalosporanic acid nucleus, runs into many thousands. Most types of the enzyme, though predominantly attacking either the cephalosporins or the penicillins, will hydrolyse some members of the other group of compounds at a significant rate. It is the Gram-positive species that produce enzyme

with the highest activity and also in greatest quantity. This, when the relevant gene is maximally active (full “derepressed”), may amount to about 2% of the total bacterial dry weight, or probably over 3% of its protein.

In most of these strains the system is inducible: the penicillinase gene is usually strongly repressed, and production of the enzyme is minimal until a penicillin or cephalosporin is added to the culture, after which it may increase several hundredfold.

In most instances the enzymes are certainly responsible (probably exclusively) for the high degree of resistance to penicillins and/or cephalosporins manifested by the organisms that produce them. (For recent accounts of their biological, chemical, and physicochemical properties see the reviews by Pollock (1965a) and Citri and Pollock (1966).)

“Function”

The penicillinases of Gram-positive bacteria are among some of the most active enzymes known: second only to catalase. Their specific activities, expressed as turnover numbers (molecules of substrate split by one molecule of enzyme per minute at 30° C.), range around 1.5×10^5 (Pollock, 1965b).

Nevertheless, there are certain difficulties in accepting what many believe to be the naive assumption that the main or sole function of penicillinase, in the orbit of the organism that produce it, is to destroy penicillin.

The objections raised can be classified under four main headings. I will deal with them systematically and try to produce the counter arguments as we go along.

1. Substrate Specificity

It has been claimed that the enzyme may have a broader specificity than that provided by the β -lactam bond of penicillins and cephalosporins (Saz and Lowery, 1964; Saz *et al.* 1964). The a priori argument is that the penicillin nucleus is really only a condensation of two amino-acids, L-cysteine and D-valine, with an additional cross-bridge, and that the CO-N bond split is only a modified peptide link (Fig. 2). Penicillinase, then, might be regarded as a sort of modified peptidase: its penicillin-hydrolysing ability could be “incidental.”

Original suggestions (Saz *et al.*, 1964) that certain peptides were in fact hydrolysed by what were claimed to be purified preparations of *Bacillus cereus* penicillinase have not, however, yet been substantiated or successfully repeated.

Rather more impressive were reports from these authors of the specific inducing activity of certain straight chain amino

* Being the substance of the first Almroth Wright Lecture, in the 1967 series, given at the Wright-Fleming Institute of Microbiology, London W.2, on 1 May 1967.

† Professor of Biology, University of Edinburgh.

cyclic oligopeptides, on wild-type inducible penicillinase systems in *Staphylococcus aureus* and *B. cereus*. Their findings have not yet been consistently reproducible in all laboratories where they have been investigated. But the idea behind them is a particularly interesting one, and only a few weeks ago further reports appeared from Saz's laboratory (A. K. Saz, personal communication) claiming that induction of *B. cereus* penicillinase had been demonstrated with extracts from the cell walls of *Staph. aureus* containing muramic acid and peptides. The suggestion here, again, is that penicillinase is really a modified peptidase, perhaps one originally mainly concerned

FIG. 2.—Basic structure of penicillin viewed as a cyclic dipeptide: L-cysteinyl-D-valine.

in cell-wall metabolism; but in any case not originally or primarily orientated towards the β -lactam ring of penicillins and cephalosporins.

We shall consider the possible relation of the enzyme to cell walls, from an evolutionary point of view, later on. But at the moment it is essential to point out that:

(a) No isolated and identified substance other than penicillins and cephalosporins has ever been unequivocally shown to act as substrate for purified preparations of β -lactamase—that is, so far as possible uncontaminated with other enzymes. Even if some slight peptidase activity had then been demonstrated it would hardly alter the significance of the overwhelming orientation of purified enzyme towards this particular β -lactam bond.

(b) Strains of *Staph. aureus*, *B. cereus*, and *B. licheniformis* genetically deprived of their β -lactamase activity—be it through a point mutation in the penicillinase gene or a complete deletion by plasmid elimination from the cell—show a profound loss in resistance to the penicillins. As might be expected by reason of its extracellular location and detoxifying action, the enzyme is a collective weapon against the antibiotic and does not often, in these organisms, give much protection to single isolated cells. But if resistance is tested with whole populations the effect of penicillinase can be shown to increase their penicillin-resistance by several orders of magnitude—for example, from 0.01 unit to several hundred units/ml. in *Staph. aureus*, and from 0.01 unit to several thousand units/ml. in *B. cereus* and *B. licheniformis* (M. R. Pollock, unpublished observations).

Significance of Low Penicillinase Activities

Many (fully induced) Gram-positive bacteria produce very high levels of activity—5,000 units per mg. dry weight being not at all unusual. However, among Gram-negatives—in particular the coliforms—activities may be so low (<1 unit per mg. dry weight) that it is difficult, at first sight, to believe that it could be of any value to the cells as an anti-penicillin agent. Moreover, there is often rather little apparent correlation between penicillin and cephalosporin resistance among coliforms and levels of their β -lactamase, as measured in the laboratory.

There are, however, a number of factors operative in this sort of comparison which make an assessment of function extremely difficult:

(a) Strains differ considerably in their “intrinsic” susceptibility to penicillins and cephalosporins. This, possibly, is a question of the sensitivity or accessibility of cell-wall synthesizing enzyme systems to these antibiotics; at all events it has nothing directly

to do with penicillinase. Many penicillinase-producing coliforms have a high intrinsic resistance, and the extra margin of resistance contributed by β -lactamase might be expected to be, for that reason, smaller than for those organisms with low intrinsic resistance.

(b) It may be most misleading to translate enzymic activities, as usually measured in the laboratory, into enzymic function in vivo under natural conditions. There are here three main relevant factors to be taken into consideration, as follows:

(i) The chemical and physical cell relationships and extra-cellular environment may be very greatly and significantly different in nature—for example, in the soil or in animal and plant tissues—from those normally operative in laboratory assays, where enzyme solutions or homogeneous cell suspensions have normally to be used. The degree of cell clumping, the local concentrations, and “feed-in” supply of substrate, etc., may be expected to be particularly important in relation to detoxifying enzymes.

(ii) The location of the enzyme with respect to the cell may be of vital significance. There may be advantages for an intrinsically sensitive cell to produce a penicillinase that is extracellular (like *B. cereus*, *B. licheniformis*, and some strains of *Staph. aureus*) for “clearing a way free of penicillin” in order to prevent the antibiotic actually reaching the susceptible cell itself (Pollock, 1962). But this involves a huge dilution effect, so that large quantities of the enzyme would need to be produced (as indeed appears to be the case with exo-penicillinase-forming organisms).

With different types of cell it may be more effective to have very small amounts of enzyme strategically located next to the cell-wall synthesizing enzyme systems on the surface of the cell—or attached to the membrane, as might indeed be the case with many of the coliforms which have small quantities of enzyme firmly and completely bound to cell structure (Smith, 1963a; Smith and Hamilton-Miller, 1963; Hamilton-Miller, 1963). It would be of great interest to know whether this enzyme is concentrated at “growing points” on the cell surface (in so far as they may be restricted in number and location), where active synthesis of cell-wall material is occurring—see reviews by Salton (1964) and Rogers (1965).

(iii) Enzymic efficiency in vivo can probably only rarely be gauged by measurement of maximal activity (“ V_{max} ”) in enzyme assays. This is because, in the latter, the enzyme is, by definition, always saturated with its substrate, whereas there are good reasons for believing that in the intact cell most metabolites are at very low concentrations, and their enzymes are therefore highly unsaturated. Operational enzyme activity is determined as much by affinity for the substrate as by turnover number. This means that in vivo the rate of the reaction catalysed by one unit of any given enzyme is governed as much by the concentration of its substrate as by its maximum specific activity.

These considerations apply especially to the penicillinases, where the affinity constant or “ K_m ” (defined as the substrate concentration at which the enzyme functions at 50% maximal efficiency), when measured for the common penicillins, is nearly always well above the minimal growth inhibitory concentration of the antibiotic.

A more valid measurement for any particular variety of the enzyme would therefore be one which has been referred to as “physiological efficiency,” being defined as V_{max}/K_m (Pollock, 1965b). This is directly proportional to the rate of substrate hydrolysis under conditions of gross enzyme undersaturation, and allows direct comparison between different penicillinases at any given penicillin concentration. By using this value it has been possible to show that varieties of penicillinase from the same species may differ at least sixfold in V_{max} but not significantly at all in physiological efficiency. The reason for this can be interpreted quite simply in enzymological terms; but the essential point here is that there is no difference between the rate at which they hydrolyse penicillin at the low concentrations normally expected in nature.

These factors still, of course, do not take into account further discrepancies that may arise between enzymic measurements on soluble extracts (which are necessary for controlled enzymological work) and those made in vivo with enzyme that is bound to intact cells. With whole cells, substrate-accessibility barriers (Smith, 1963b; Smith and Hamilton-Miller, 1963; Sabath *et al.*, 1965; Ayliffe, 1965; Hennessey, 1967) and/or factors altering the shape or “conformation” of the enzyme molecule associated with its binding to other

structures may often be operative and affect what might be termed the "cellular efficiency" of an enzyme.

(c) In certain instances normal, penicillin-sensitive wild-type strains of bacteria may be found to produce measurable but exceedingly minute quantities of penicillinase (Ayliffe, 1963, 1965; Smith and Hamilton-Miller, 1963; Eriksson-Grennberg *et al.*, 1965). It would seem at first sight to be an utterly useless activity. However, in some instances cells mutate spontaneously to form greatly increased quantities of the identical type of penicillinase. They thereby acquire greatly increased penicillin-resistance (Pollock, 1957; Eriksson-Grennberg *et al.*, 1965).

The classical case is that of a variety of *B. cereus* studied by Sneath (1955), where overnight culture of the original penicillin-sensitive strain in broth containing 1 unit of benzylpenicillin/ml. permitted its conversion to a new ("mutant") population of cells forming the same enzyme at 5,000 times the previous rate, with 300 times the resistance to the antibiotic—even when tested against single cells. The phenomenon was unequivocally shown to be due to a spontaneous mutation (presumably in some type of regulatory gene), the effect being to cause complete derepression of a pre-existing penicillinase structural gene, followed by selective overgrowth of the mutant by the penicillin present.

Previously, such combined mutation-plus-selection phenomena in bacteria were termed by Stanier (1953) "evolutionary adaptation" to distinguish them from "physiological adaptation," which included enzymic adaptation processes involving all the cells in a population and no change in genotype.

I do not, however, believe that this particular phenomenon has anything at all to do with evolution in the general sense. Rather it would seem to be a mechanism of biological adjustment, itself evolved as a type of populational adaptation to meet the needs of a whole community of individuals in the face of an intermittently intruding situation. Such a situation—the presence of toxic quantities of penicillin—may be supposed to have been previously encountered often enough to have allowed the acquisition of a fully fashioned structural gene for an enzyme which, however, is kept rigidly repressed (for economy of effort), apart from occasional "release" mutants which can be immediately selected by the penicillin if and when it presents itself in the environment.

3. Formation of Penicillins and Cephalosporins in Nature

So far, attempts to demonstrate the formation of these antibiotics in soil under natural conditions have not been successful, and a certain scepticism has developed about whether they are even indeed capable of being produced except as laboratory freaks (see Brian, 1957).

There are, however, several reasons why it might be difficult to isolate them from the soil: they are likely to be present in extremely low concentrations; they may be rapidly destroyed by the chemical environment or adsorbed on soil surfaces; and they may, indeed, be hydrolysed by the penicillinase formed by the large numbers of *B. licheniformis* and *B. cereus* cells undoubtedly present in most types of soil all over the world.

It does not really seem that attempts to demonstrate their formation have been anywhere near exhaustive.

Moreover, recently a strain of *Penicillium chrysogenum* has been coaxed to form penicillin, by growth on the surface of sterilized soil—rather capriciously, admittedly—and will form the antibiotic more regularly, under strictly controlled conditions, in aqueous soil extracts containing only lactose as additional nutrient factor (P. Hill, private communication).

4. Physiological Role of Penicillins and Cephalosporins

It is also sometimes argued that even if these antibiotics are formed under natural conditions they can be nothing other than waste products which are fortuitously toxic to certain bacteria. It is further argued that, in any case, susceptible bacteria must meet the antibiotics only very rarely, and it is

therefore unlikely they would have evolved enzymes specially to deal with them.

There are quite a number of points that must be emphasized here:

(a) Penicillins and/or cephalosporins are not rare oddities in the fungal world, as was once supposed. Table I lists no fewer than nine distinct genera of microfungi—comprising a total of at least 36 species (there are probably in reality many more)—that produce one or both of these two classes of antibiotic. All these genera may inhabit the soil at one time or another, and three out of nine are dermatophytes, normally saprophytic on skin and/or other keratinized body surfaces.

TABLE I.—Microfungal Genera Forming Penicillins and/or Cephalosporins

<i>Aspergillus</i> (7 species) (see Sanders, 1949; Cole, 1966)
<i>Cephalosporium</i> (see Abraham, 1962)
D <i>Emicelopsis</i> (see Kavanagh <i>et al.</i> , 1958; Uri and Valu, 1963)
D <i>Epidermophyton</i> (Uri and Valu, 1963; Cole, 1966)
<i>Maibranchea</i> (see Sanders, 1949)
<i>Paecilomyces</i> (Pisano <i>et al.</i> , 1961)
<i>Penicillium</i> (23 species) (see Sanders, 1949; Cole, 1966)
<i>Streptomyces</i> (Miller <i>et al.</i> , 1962)
D <i>Trichophyton</i> (see Sanders, 1949; Uri and Valu, 1963; Smith and Marples, 1964; Cole, 1966)

D=Dermatophytes.

(b) All the main penicillinase-producing species of bacteria are either natural inhabitants of soil and water in large numbers (*B. cereus* and *B. licheniformis* and *Pseudomonas*) or are found there from time to time (such as *Aerobacter*, *Klebsiella*)—or they are typical skin saprophytes (*Staphylococcus*). In other words the natural environments of penicillin-formers seem to be similar to, if not identical with, those of penicillin-destroyers.

It is probable that strains of *Penicillium* or *Aspergillus* are not infrequently present together with *B. cereus*, *B. licheniformis*, or *Pseudomonas* in the same sample of soil (Holding *et al.*, 1965). And penicillinase-forming *Staph. aureus* has been found coexistent with penicillin-forming *Trichophyton* on the skins of hedgehogs in New Zealand (Smith and Marples, 1964).

There seems no need to puzzle why some strains of *Staph. aureus*, isolated in 1937 well before the therapeutic era of penicillin, were found to produce the same penicillinase in just as potentially large amounts as that formed by "modern" post-penicillin strains. Therapeutic penicillins have, of course, certainly enormously increased the incidence of penicillinase-positive strains of staphylococci—presumably by natural selection (see Ciba Foundation, 1962). But they have not detectably altered the nature of the penicillinase genotype (M. H. Richmond, private communication). It can be argued that the evolutionary stimulus had already been there previously—perhaps for many millions of years.

(c) Finally, it seems a priori probable that most soil organisms are engaged in a perpetual struggle for survival in an environment where supply of nutrients is a constant factor limiting growth and multiplication. Any weapon reducing the growth rate of a competitor might be expected to help survival and further growth of the organism producing it.

It is indeed possible to demonstrate, in the laboratory, that both *P. chrysogenum* and *B. licheniformis* inoculated together (the latter somewhat after the former) into the same soil sample will grow to a final total number which is considerably lower than that attained by either alone, when inoculated into an aliquot sample separately (M. R. Pollock, unpublished experiments).

The stage could therefore be said to be set for a battle between the microfungi and the bacteria, such as to encourage the evolution both of the penicillins and cephalosporins on the one hand and of the enzymes to hydrolyse them on the other.

Moreover, it must be remembered that penicillinase is known only among those organisms with *N*-acetylmuramic acid-containing mucopeptide in their cell walls (the synthesis of which is specifically inhibited by the penicillins) which are sensitive to, and threatened by, penicillin. If penicillin hydrolysis is only an incidental by-reaction of another type of enzyme activity with real physiological significance, why is it not found in organisms that do not have to bother about penicillin?

At least it can be said that the situation, as thus analysed, makes teleological sense.

The evidence is, however, circumstantial, and it must be accepted that this interpretation remains highly questionable. All that can be claimed is that it is not unreasonable.

"Origin"

1. Physiological Adaptation

(a) In general, most wild-type penicillinase-producing strains of bacteria isolated in the absence of penicillins and cephalosporins show very low enzymic activity. However, nearly all Gram-positive strains and a proportion of Gram-negatives are typically penicillinase-inducible, and respond rapidly to treatment with the antibiotic by increasing rates of enzyme formation up to 300 times the "basal" level. No permanent genetic change is involved, and the cultures revert to their usual uninduced level of production after a period of growth in the absence of inducer (see Pollock, 1959).

I do not propose to deal further with this well-known phenomenon of enzyme induction here. It is as vital a part of resistance to the antibiotics as direct enzymic action itself.

(b) As mentioned previously, there is another method by which wild-type "micro-constitutive" strains—both among Gram-negatives (Eriksson-Grennberg *et al.*, 1965) and Gram-positives (Sneath, 1955)—can increase their rate of penicillinase formation: what I have called a *populational adaptation*, involving an apparently spontaneous mutational event in a very small proportion of a population, derepressing the penicillinase structural gene to allow its full expression, followed by selection of such mutationally altered cells in the presence of a penicillin concentration which will suppress the growth of the rest of the population.

Although the change is genetically fairly stable, it will materialize rapidly, and there are grounds for regarding it as a physiological type of adaptation when applied to the whole population.

2. Genetic Control

(a) The populational adaptation referred to above can also, of course, in another context, be regarded as a genetic type of acquisition of increased penicillinase activity.

(b) More fashionable, and better studied at the moment, is the mechanism by which cells can acquire penicillinase activity—from scratch, so to speak—by acceptance of extrachromosomal factors (episomes or plasmids) which can carry the β -lactamase gene complex in a state that is partially autonomous from the chromosome, but otherwise functions in the coding and control of formation of the enzyme as do the chromosomal genes.

In coliforms the penicillinase genetic system may constitute part of an extrachromosomal "R" or resistance factor, which, by linkage up with a "T" or transfer factor, may pass from one cell to another spontaneously (not necessarily within the same species) in the process referred to as "infectious heredity" (Datta and Kontomichalou, 1965).

In *Staph. aureus*, "penicillinase" plasmids can be transferred from one cell to another—not (so far as is known) spontaneously, but by transduction through an infecting bacteriophage (see Richmond, 1965a; Novick, 1967). It is possible, with staphylococci, for the cell to possess more than one type of penicillinase plasmid at the same time. And in this organism it seems likely that the same or analogous penicillinase genes can, in certain strains, exist fully integrated on the chromosome (Asheshov, 1966), though there is yet no clear evidence that they can pass reversibly from the extrachromosomal to the chromosomal state like episomes.

3. Evolutionary Origin

When we come to consider the problem of evolution we enter the realms of high speculation. In spite of the fact that we accept the fact of organic evolution unquestioningly—at least I *suppose* we do—we know extremely little about its mechanism. Yet so many biologists seem tacitly to assume, rather uncritically, its neoDarwinian basis and its occurrence through a process of natural selection operating on random "spontaneous" mutations and recombinational events in the genome.

With the rise of molecular biology it is now possible to visualize possible steps at a chemical level and be a great deal more precise in our hypotheses.

Unfortunately we do not yet know the exact amino-acid sequence of any type of penicillinase—though such an analysis for one of the staphylococcal varieties is only just short of completion (R. P. Ambler, private communication). Nothing, of course, is known about the base sequences in the relevant deoxyribonucleic acid of its gene. So speculations must be linked to rather more general considerations of function and properties.

At the beginning of this lecture I emphasized the variety in properties of the different penicillinases, particularly in immunology, substrate profile (relative activities on various penicillins and cephalosporins), and overall amino-acid composition.

I now wish to do the reverse and point out the similarities which are (perhaps a little tendentiously) stressed in Table II (see also Pollock, 1967). The number of individual amino-acid residues may differ considerably, but the combined basic and combined acidic amino-acids are fairly similar; cysteine is absent; the specific activities range only over a factor of 10 (which is very narrow considering the wide range of values for enzymes in general) and the "physiological efficiencies" (previously defined) only fourfold.

TABLE II.—Properties of Penicillinases from Different Bacterial Species

	<i>B. cereus</i>	<i>B. licheniformis</i>	<i>Staph. aureus</i>	<i>E. coli</i>
No. of varieties examined	2	2	2	1
Molecular weight	31,000–35,000	28,000	29,000	16,700
N-terminal amino-acid	Asp.	Lys.	Lys.	
Amino-acid composition (No. of residues per molecule):				
Cysteine	0	0	0	
Lysine + arginine	40–43	38	48–49	
Aspartic + glutamine	60–69	64–66	57–64	
Total hydrophobic	67–85	75	66–75	
Differential rate of synthesis (μ g. enzyme/mg. dry bacterial weight)	9–11	11–12	8–9	1.0
Molecular activity $\times 10^6$ (No. molecules benzylpenicillin hydrolysed/molecule enzyme/min. at 30° and pH 7)	1.5	0.2–1.1	0.2	0.19
Physiological efficiency $\times 10^6$ (for definition, see text)	5–6	5–6	16	4

From data summarized by Citri and Pollock (1966).

Though the amino-acid compositions of the *B. cereus* and *B. licheniformis* varieties are as different from each other as either is from the staphylococcal enzyme, there is a striking though quantitatively slender immunological cross-reaction between these two (Pollock, 1967), which would indicate some partial homology in tertiary structure and therefore probably elements of amino-acid sequence resemblances which may also occur in other types. There are, however, no similar peptides found on tryptic hydrolysis of the staphylococcal and *B. licheniformis* enzymes (R. J. Meadway, private communication).

The molecular weights of the varieties from Gram-positive organisms are almost identical, whereas that from *Escherichia coli* (Datta and Richmond, 1966) is about half that of the

others. There is good evidence that in all varieties there is only one N-terminal amino-acid residue, and therefore a single peptide chain, and it could be argued (as in the case of haemoglobin chains—Fitch, 1966) that the Gram-positive variety originated from an "internal" duplication of the more primitive Gram-negative chain.

There is perhaps significant evidence supporting some extent of common pathway in the evolutionary history of these enzymes. It seems unlikely that the degree of biological and structural similarity evidenced could have occurred from a purely convergent line of development.

Be that as it may, we shall assume for the moment that the penicillinases have had a common evolutionary origin, though it is not strictly necessary to do so for the argument I shall develop.

I shall also accept two other propositions, both of which are reasonable and in fashion—but very far from being proved:

(a) That the structural genes for most existing enzymes have evolved through modification of pre-existing structural genes for other enzymes which must inevitably be closely related in amino-acid sequence and therefore probably similar in biological specificity.

(b) That the most plausible mechanism for ensuring the stability of useless intermediary steps in the evolution of one enzyme from another during the period before a significantly useful version had emerged would be through preservation of the existing enzyme by an initial duplication of the relevant gene. In diploid organisms this might not be necessary, at least not at the first stage. In haploids it would be immediately essential and in diploids eventually so, except in so far as such evolution could be by substitution rather than by addition. The expansion of the genome through phylogeny must imply that most evolution has been through addition.

The mechanisms by which the "second copy" is modified need not really concern us here. It could be through genetic shuffling: by recombination, translocation, deletion, or inversion; but in most cases probably through a sequential series of point mutations.

In what direction do these two assumptions point?

Taking the latter first, it is implied that evolution might proceed faster in diploids because initial modifications to one allele would be automatically protected in their early "useless" stage, at least in heterozygotes, without having to wait for linear reduplication. Homozygotes, however, would become lethal and highly disadvantageous, and so duplication would tend to follow at some stage.

So far no bacterial species have been found to be completely diploid, but temporary partial diploids are frequent in staphylococci (Novick and Richmond, 1965; Novick, 1967)—either in the sense of two allelic extrachromosomal plasmids or plasmids plus chromosomal alleles. In that sense—which could, however, be relatively unimportant—the situation may have

been favourable for the evolution of penicillinase, whose genes are now known to be capable of forming diploids—at least under laboratory conditions (Richmond, 1965b).

The first assumption implies that we should look for the evolutionary origin of penicillinase among enzymes attacking or combining with molecules resembling penicillin. And where better should this be done than among those dealing with the biosynthesis of the cell-wall mucopeptide, a process we know to be specifically inhibited by penicillin (see Park, 1966) and one of whose enzymes, therefore, is a likely candidate?

Fashions change in the interpretation of penicillin antibiosis. At the moment the reactions in cell-wall synthesis which have most attention in staphylococci are ones directly involving the exchange of the terminal D-alanine residue of the oligopeptide chain attached to muramic acid, with the first glycine of the pentaglycyl peptide attached to L-lysine of a near-by oligopeptide chain. This reaction, which may be one of the last of the sequence in cell-wall synthesis, thus forms a cross link between two such peptide chains (see Fig. 3). It has in fact been shown to be extremely sensitive to inhibition by penicillin *in vitro* (Wise and Park, 1965).

It has also been pointed out (Collins and Richmond, 1962) that *N*-acetylmuramic acid shows a strong three-dimensional structural analogy to penicillin (though superficially there is little resemblance between their chemical formulae). Tipper and Strominger (1965), however, stress rather the analogy with d-ala-d-ala, emphasizing that penicillin is a modified peptide, and that the penicillin-sensitive transpeptidation reaction itself is a type of peptidase (which, it has been argued, is also true of penicillinase). Ironically, Wise and Park (1965) and Park (1966) stress rather the L-alanyl-γ-D-glutamyl part of the cell-wall molecule as being most closely analogous to penicillin.

It has in fact been claimed in Saz's laboratory—as mentioned previously—that extracts of *B. cereus* cell wall can induce penicillinase in this organism. Induction tests are very sensitive, and they are easier to perform than tests for substrates. They can thus reasonably be taken, if properly controlled, to indicate the possibility of enzymic affinity for the substances as substrates; though it certainly does not necessarily follow that inducers are substrates—or indeed complexants of any kind—for the enzyme. (We have, however, tested *N*-acetylmuramic acid and the d-ala-d-ala dipeptide as inducers for the enzyme in *Staphylococcus* and *B. cereus* without finding a trace of activity.)

If the *N*-acetylmuramic acid/penicillin analogy is significant another candidate for ancestry would be the extracellular bacterial lysozyme first described in *Bacillus subtilis* (Richmond 1959) but probably also produced by many other species. Like the lysozyme from egg-white, this enzyme probably attacks the cell-wall mucopeptide by hydrolysing the *N*-acetylmuramic acid/*N*-acetyl glucosamine bond. It might therefore conceivably be structurally related to penicillinase.

Indeed, following the elucidation of the tertiary structure of egg-white lysozyme by Blake *et al.* (1965) it was reported by Johnson (1967) that this enzyme does indeed bind penicillin to a significant extent, at a site which also binds derivative of *N*-acetylmuramic acid. Penicillin, moreover, was also found to inhibit the action of lysozyme. The groups of the molecule that appear to be involved in this binding reaction with lysozyme are not, however, apparently those originally thought to form the basis for the postulated homology with *N*-acetylmuramic acid (Collins, 1967). The significance of this reaction remains therefore uncertain.

Other interesting candidates would be: (a) the enzymes in lysostaphin (Schindler and Schuhardt, 1964, 1965) among which may be some peptidases responsible for splitting the d-ala-gly bond that is formed by the transpeptidase previously mentioned as being specifically inhibited by penicillin; and (b) the "competase" described by Young *et al.* (1964) which splits the link between *N*-acetylmuramic acid and the L-ly-

FIG. 3.—Basic unit structure of staphylococcal cell wall, drawn to indicate the two last steps (a and b) in the specific penicillin-sensitive transpeptidation reaction which completes the bridge (c) between the two different oligopeptide chains, and thus finally rigidifies the whole macromolecular complex into a stable molecular exoskeleton for the cell. Based on an article by Wise and Park (1965). Mur.NAc=*N*-acetylmuramic acid. Gl.NAc=*N*-acetyl glucosamine. Abbreviations for amino-acids as suggested by the *Biochemical Journal*, 1967, 102, 3.

residue that is the first of those making up the peptide "side-chain," and confers transformation competence on *B. subtilis*.

What of course is needed here is the isolation and characterization of these cell-wall enzymes in order to see if there are any amino-acid sequence homologies or other types of resemblances between them and the relevant penicillinase.

However, the fact remains that penicillin does inhibit a step or steps in cell-wall biosynthesis quite specifically, and this must almost inevitably mean that it combines specifically with one of the enzymes involved. Moreover, penicillin is known to combine with high affinity, and very specifically, with some sort of receptor site (the P.B.C. or "penicillin-binding-component"—see Cooper, 1956) which is present only in those organisms that are highly susceptible to penicillin. This component could logically be one of the cell-wall synthesizing enzymes, and it is not unreasonable to suppose it might have evolved, through modification of the site that combines with penicillin, to become capable of hydrolysing the antibiotic instead of simply being inhibited by it. This possibility, and related ones, have been discussed recently by Boman *et al.* (1967).

Evidence

In attempting to tackle the general problem of penicillinase evolution itself, is it possible to obtain any direct evidence of the mechanism?

We have made efforts along these lines of approach as follows:

(a) Palaeoenzymological Evidence

In a survey of a wide range of different present-day isolates of *B. licheniformis* from all over the world, strains could be sharply classified into two groups according to the properties of the penicillinase they produced (Pollock, 1965b). The enzyme occurred in two related but quite distinct molecular types, differing by only a very few (probably two or three) amino-acid residues and a number of enzymological properties.

Accordingly, when Sneath (1962) revived some spores of *B. licheniformis* which had lain dormant in the dried soil stuck to the roots of some plant specimens preserved untouched in the British Museum since 1689, the opportunity was seized of examining the properties of the penicillinase produced by the strains found (M. R. Pollock, unpublished experiments). They all fell clearly into one of the two types existing at present: their substrate profiles and immunological reactions indicating that no evolutionary change had occurred at least during the last 270-odd years—a short enough time, of course, in absolute terms; but in terms of the maximum possible number of cell generations, equivalent to 100 million years or so on the scale of human generation time, and therefore presumably long enough for evolution to have occurred if cell generations were the main operative factor.

(b) Laboratory Studies

"Blind training" of the existing penicillinase genome by serial subcultures of *B. licheniformis* in marginally inhibitory concentrations of the new penicillins, such as methicillin, did not give rise to cells producing penicillinase with increased ability to hydrolyse the compounds in question.

Attempts to follow sequential mutations in the penicillinase structural gene, isolated after mutagen treatment of *B. licheniformis*, that might have some physiological significance in changed enzyme specificity yielded nothing of interest. It was, however, possible to show that single-step, presumptive point mutations, supposedly involving single amino-acid residue substitutions in the molecule, could produce a complete inversion of relative penicillinase and cephalosporinase activities (M. R. Pollock, unpublished observations). In other words, a single-step mutation could result (in two instances: see Fig. 4) in an enzyme originally predominantly

a cephalosporinase. But in neither case was there a clearly significant absolute increase in specific activity. It could therefore hardly be claimed that the change was one that must have evolutionary significance. Nevertheless, it might be the first step in a significant evolutionary sequence, and these instances at least indicate the considerable alteration in substrate specificity that may result from a single mutation, and can be regarded as possible examples of the sort of event that may be occurring in the process.

FIG. 4.—A mutational "conversion" of penicillinase into cephalosporinase. Comparisons of specific activities (units/μg. protein) in hydrolysing penicillin and cephalosporin of wild-type and mutated penicillinases produced by two different strains of *B. licheniformis*. ■ Penicillinase (benzylpenicillin as substrate). □ Cephalosporinase (benzyl ceph. C as substrate for 6346 strains and cephaloridine for 749 strains).

It is conceivable that the type of modification observed here is not far removed from the naturally developed change that may be presumed to have occurred in the past in the evolution of the two extracellular β-lactamases of *B. cereus* recently separated and characterized by Kuwabara and Abraham (1967). These two types (one of which is predominantly, if not exclusively, a penicillinase (β-lactamase-1: the original α-penicillinase) whereas the other has approximately equal activity on cephalosporins and penicillins (β-lactamase-2)) differ in thermostability, activation by Zn⁺⁺ and other characters. Their comparative structural properties are so far unknown. But in their response to induction and the simultaneous conversion of the systems controlling their formation to constitutivity, by a single mutational step, they behave as if their genes were components of one operon—that is, contiguously located on the chromosome and under a single control system. They may therefore, for this reason alone, be considered to be possibly evolutionarily related.

(c) Field Survey

The advent, and therapeutic use on a wide scale, of the new penicillins, such as methicillin, cloxacillin, and oxacillin, which are very resistant to hydrolysis by staphylococcal penicillinase, raised the possibility that the organism might respond by developing a modified enzyme that would more effectively destroy these compounds. The prospect of following the evolution of a new enzyme with biochemical and genetical checks at every stage seemed an interesting possibility. Accordingly, a systematic biochemical survey of newly isolated strains of staphylococci showing increased resistance to methicillin was instituted at the Central Public Health Laboratory, Colindale.

The results so far have been unequivocally negative. Increased methicillin-resistance has undoubtedly occurred, and the number of isolates showing some rise in resistance to methicillin has increased. But no new type of enzyme has emerged, and there has been no significant increase in the quantity of enzyme produced (Richmond, 1966; K. G. H. Dyke, unpublished results).

The increase in resistance, which in any case has been modest, is of the "intrinsic" variety and could be due to a cell-wall

synthesizing machinery with a greater capacity for standing up to the penicillinase-resistant penicillins than that predominating in pre-methicillin days. Its biochemical nature and the mode of its emergence remain a mystery.

The most important single factor contributing to the development of penicillin resistance in staphylococci in recent years would appear to be probably the infectious spread of penicillinase plasmids mentioned previously.

Conclusion

All these scrappy and indecisive points, the indirect and circumstantial evidence, and the speculative and perhaps tendentious arguments may seem rather naive and primitive attempts for tackling so difficult and huge a problem as biochemical evolution, albeit of a single enzyme-type. But here and there a few indications and direction pointers have emerged, most of them leading towards a demand for greater information on the amino-acid sequences of more and more enzymes. And if the time-scale for evolution may still be wrong for a direct experimental approach (we really do not know about this) it is through the analysis of bacterial proteins at a biochemical level that we may still hope to have the best chance of obtaining some significant results.

Summary

The enzyme, generally known as "penicillinase," that hydrolyses the β -lactam bond of penicillins and cephalosporins, with production of the antibiotically inactive penicilloic and cephalosporic acids, exists in a number of different forms, produced by a wide range of Gram-positive and Gram-negative bacterial genera (*Bacillus*, *Staphylococcus*, *Escherichia*, *Klebsiella*, etc.).

Despite some striking chemical and biological differences, there are probably significant resemblances between most of the varieties of penicillinase that have been studied in purified preparations. This supports the hypothesis of a common or closely related evolutionary origin.

The restricted specificity and high detoxifying activity of most penicillinases suggest that their physiological functions and evolutionary pathways are specifically related to the antibacterial action of the penicillins and cephalosporins. Moreover, the production of these antibiotics is more widespread among soil and dermatophytic microfungi than is commonly supposed, and the natural distribution of penicillin-producing micro-organisms seems to correspond fairly closely to that of penicillinase-producers.

The recent demonstration of significant penicillin production by *Penicillium* growing in soil unsupplemented by "artificial" nutrients suggests that previous scepticism regarding formation of the antibiotic "in nature" may not be justified, and that the penicillin/penicillinase relationship may be of importance in soil ecology.

Consideration of the evolutionary origin of penicillinase remains highly speculative, though it is clear that the various forms of the enzyme, as we now know them, pre-existed the therapeutic penicillin era, the only effect of which, in this context, has been to increase by natural selection the proportion of bacteria producing them.

Search for a possible penicillinase-ancestor is focused on the only other known class of protein that must, on a priori reasoning, be capable of specific combination with penicillin—that is, one or other of the enzymes involved in biosynthesis

of the mucopeptide of the bacterial cell wall, a reaction known to be specifically inhibited by this antibiotic.

Direct Exchange Blood Transfusion in Treatment of Hepatic Coma

J. A. McLEAN,* M.D., M.R.C.P., F.R.A.C.P., M.C.P.A.; H. A. LUKE,* M.B., D.D.R., F.C.R.A., F.F.R.

Brit. med. J., 1967, 4, 78-80

The first recorded case of recovery from hepatic coma after an exchange blood transfusion was that of Lee and Tink (1958). They gave two exchange transfusions of fresh blood to a boy aged 13 who was deeply jaundiced and comatose. After the first transfusion of 3,260 ml. his condition was unchanged, but when a second exchange of 3,140 ml. was given he improved and recovered completely.

Trey *et al.* (1965) reported seven cases treated by exchange transfusion. Approximately twice the patient's blood volume was exchanged. Freshly donated heparinized blood was administered under pressure on the venous side while blood was simultaneously removed from an artery. Five of the seven cases recovered completely. They were fully reported by Trey *et al.* (1966). Berger *et al.* (1966) put on record another recovery from fulminating hepatitis after exchange transfusion.

In the above cases fresh heparinized blood was used, and it is the purpose of this paper to describe a technique for directly giving large quantities of unmodified blood.

Materials and Method

Rotary pumps designed by Julian Smith (1941) for direct transfusion were used. Rubber tubing was replaced by polyvinyl tubing (Portex size 12E), which gives a better flow rate and is translucent. A disadvantage of polyvinyl tubing is that at low temperatures it is inelastic, so sterilization is carried out in boiling water immediately before the transfusion to ensure that the tubing is warm and elastic when used. Julian Smith transfusion needles with an inside diameter of 1.6 mm. and highly polished internal surface are used to withdraw blood from the donors.

Plastic catheters for the recipient are prepared from Teflon tubing with an internal diameter of 1.5 mm. Percutaneous catheterization of veins is performed with the Seldinger (1953) technique.

The rotary pumps are mounted on two bridges—one on each side of the patient. On the donor side a clamp for holding a flask of sterile normal saline is attached to the bridge.

Exchange transfusions are performed under local anaesthesia. Usually from 8 to 11 donors were used, and they were examined and tested for compatibility immediately before the transfusion was begun.

The patient lies on his back with one pillow under the head and a small pad under the sacrum. The thighs are slightly abducted and local anaesthesia is injected in the skin and subcutaneous tissue just medial to the femoral artery. A small incision is made in the skin and a Seldinger needle is inserted into the femoral vein. With the usual technique the Teflon catheter is guided into the femoral vein by the flexible wire, which is then removed. The catheter is connected to polyvinyl tubing fitted in the pump, while the other end of the tubing passes into a transparent measuring cylinder into which the blood flows.

A second Teflon catheter is inserted into a vein on the other side of the patient. If there is no suitable vein at the elbow the catheter may be inserted in the other femoral vein so that it passes into the inferior vena cava proximal to the first catheter.

In the meantime polyvinyl tubing has been fitted into the second rotary pump and the tubing filled with normal saline. One end of the tubing is then taken out of the saline and connected to the Teflon catheter, which will transfuse blood into the patient.

The first donor is brought in and lies on a trolley adjacent to the patient. The transfusion needle is usually inserted in a distal direction and is not connected to the polyvinyl tubing until it is well placed in the vein (see illustration). With this technique a small amount of blood is spilt.

Blood transfusion rotary pump with polyvinyl tubing and insertion of transfusion needle in donor.

The transfusion is started by rotating both pumps simultaneously so that blood is removed from the patient at the same rate at which it is transfused. The usual rate of a direct blood transfusion is 500 ml. in four minutes. The needle is removed from the arm of the donor, who is immediately taken to a rest-room. The flask of saline is replaced and a fresh vinyl tube is fitted into the pump. The second donor comes in to give blood, and the procedure is repeated with each donor in turn until the operation is finished. Throughout the transfusion the volumes of blood infused and removed are checked and the clinical condition of the patient is assessed. The volume of saline must also be noted, and can be kept to a minimum by not connecting the vinyl tubing from the donor until the saline has been pumped out.

After completion of the transfusion the two catheters are removed and the sites of entry compressed for a few minutes.

Results

We have given direct exchange transfusions to four patients in hepatic coma. The first suffered from cirrhosis of the liver with oesophageal varices, and coma occurred after massive haemorrhages. In the other three patients coma was due to fulminating hepatitis. The clinical reports are briefly as follows.

* Alfred Hospital, Melbourne

Case 1

A man aged 53 was admitted to the Alfred Hospital on 1 July 1962. Recent investigation had shown oesophageal varices, and laboratory tests gave the following results: bilirubin 3.0 mg./100 ml.; cephalin flocculation positive (+++); S.G.O.T. 132 units; S.G.P.T. 70 units; prothrombin 60%. On the day of admission he passed three melaena stools. Haemoglobin was 7 g./100 ml. An intravenous drip was set up and he was given 4 units of acid citrate dextrose blood, 1 litre of 5% dextrose, and 0.5 litre of 0.9% saline. His condition deteriorated; he became mentally confused and had further melaenas. A second transfusion of 2 units of acid citrate dextrose blood, 1 litre of 5% dextrose, 1 litre of 0.9% saline, and 1 litre of Hartmann's solution was given, but there was no improvement. He was then given a direct blood transfusion from one donor (500 ml.), and his condition improved—he was more alert and able to answer questions intelligently. Three days later there was further haemorrhage and he became deeply jaundiced and comatose. On the eighth day after admission he was given a direct exchange transfusion from seven donors (volume 3.5 l.), but there was no improvement in his coma. He began to have convulsions, and died eight hours after the transfusion. A complete necropsy was not performed, but the abdomen was opened and the stomach and upper bowel were examined. There had been no recent haemorrhage. Histological section of the liver showed portal cirrhosis and nodular hyperplasia.

Case 2

A man aged 61 was admitted to Fairfield Hospital on 9 April 1966 suffering from infectious hepatitis. After admission his condition deteriorated—jaundice became deep, and foetor hepaticus, ascites, and flapping tremor occurred. He became increasingly drowsy, proceeding to a precomatose state. Melaena stools were passed and he vomited blood. He was given a direct exchange blood transfusion from eight donors (volume of blood 4 l.). Results of laboratory tests before and after the transfusion were as follows. Prothrombin increased from 27 to 51%. The platelets rose from 44,000 to 116,000/cu. mm. Bilirubin fell from 46.8 to 29.4 mg./100 ml. Serum protein increased from 3.7 to 4.9 g./100 ml. Clinical improvement was shown by less drowsiness, disappearance of foetor hepaticus, and no further bleeding. Two days later deterioration occurred. He developed signs of a chest infection and candida were grown from sputum and blood culture. He became anuric and died on 18 May. At necropsy the liver was shrivelled with surface abscesses. The lungs were congested, with consolidation in the upper lobes.

Case 3

A woman aged 38 was admitted into the Royal Melbourne Hospital on 4 August 1966. On admission she was drowsy and deeply jaundiced. She had foetor hepaticus and liver flap. Two days later her condition deteriorated; she became mentally confused and developed ascites. Peritoneal dialysis was begun, but without any improvement, and eight days after admission she was deeply comatose. At this stage, when extremely ill, she was given a direct exchange transfusion from eight donors (volume transfused 4 l.). Blood values showed an improvement; the bilirubin fell from 33 to 17 mg./100 ml. and platelets rose from 90,000 to 125,000/cu. mm. There was no clinical improvement, however, and she died seven hours later. At necropsy the liver was small with a wrinkled capsule (weight 730 g.). Nodules of regenerating tissue could be seen among areas of necrotic liver substance.

Case 4

A woman aged 31 was admitted to Fairfield Hospital on 15 July 1966. Eighteen days previously she had noticed jaundice, which progressively deepened. On admission she was mentally confused, with foetor hepaticus and a flapping tremor. The following day she was stuporous, jaundice was deeper, and the liver had become impalpable. On the third day after admission she became comatose and was given a direct exchange blood transfusion from 11 donors (volume transfused 5.5 l.). Laboratory tests showed an improvement—the bilirubin fell from 32 to 15 mg./100 ml., the prothrombin increased from 15 to 56%, and the platelet count rose from 180,000 to 260,000/cu. mm. Two days later, while comatose,

she was given an exchange transfusion of heparinized blood (5.5 l. was exchanged). There was no improvement in her mental state, while the platelet count fell from 169,000 to 125,000/cu. mm. and prothrombin was 34% before the transfusion and 34% at the end. Two days later another exchange transfusion of 5.5 l. of heparinized blood was given. The platelet count fell from 101,000 to 83,000/cu. mm., while prothrombin increased from 24 to 37%. There was no immediate clinical improvement, but 36 hours later she was mentally alert and rational and made a complete recovery. A further gastrointestinal haemorrhage occurred, and was controlled by a direct transfusion from two donors.

Discussion

The first and third patients were given direct exchange transfusions when in a terminal state, but in both there was no further bleeding after the infusion of unmodified blood. The main advantage of direct transfusion over heparinized blood is its better effect as a haemostatic. This was indicated by the blood tests before and after transfusion in Case 4. Both platelet count and prothrombin increased after the direct exchange transfusion, while the platelets were less numerous after heparinized blood and the prothrombin remained the same. It has been said that serious liver disease is a contraindication to heparin therapy and heparin should not be given to patients with potential or actual gastrointestinal bleeding (Griffith and Boggs, 1966).

In hepatic coma the use of citrated blood is contraindicated because of the danger of citrate intoxication and the possibility of enhanced bleeding from massive transfusion. The terminal liver failure in the first patient may have been contributed to by massive haemorrhages and replacement by citrated blood. If direct blood transfusion had been given initially bleeding could have been controlled.

Platelets and coagulation factors transfused by the direct method have a limited survival period and if bleeding is persistent repeated transfusions are necessary. In the treatment of hepatic coma repeated exchange transfusions have been advocated. In the second case, where only one exchange transfusion was given, death occurred subsequently from infection; whereas in the fourth patient a direct exchange transfusion was followed by two heparinized blood transfusions and a further small direct transfusion. This patient probably recovered because she was kept alive long enough for regeneration of a sufficient number of liver cells.

Direct exchange of unmodified blood has advantages but also the disadvantage of a more difficult technique. Firstly, suitable donors must be obtained, and in Melbourne the Red Cross Blood Transfusion Service has a special list of donors available for emergency. Secondly, the technique must be learnt and practised—it is not suitable for occasional use only.

With plastic materials and a rotary pump there is minimal difficulty from blood-clotting, and the only hazard is the donor, who must have good veins to ensure a rapid flow of blood. The usual practice is for the donor to wait in the rest-room with his forearm immersed in an arm bath of hot water.

In cases of hepatitis the risk of infection of donors is to be considered and special precautions are necessary. The donor is separated from the patient by a plastic screen—he is in the room for a few minutes only and does not have contact with the recipient except through the polyvinyl tube. Obviously the flow of blood must be in the one direction, but even if it was accidentally reversed it would take several turns of the pump to bring blood from the patient to the donor.

We have successfully given more than 100 direct exchange transfusions without risk to the donors.

Summary

The technique of exchange blood transfusion by the direct method is described. Two transfusion pumps are rotated

simultaneously to give blood from donors and remove blood from the patient. Polyvinyl tubing and Teflon catheters are used to lessen the risk of blood-clotting. In four patients suffering from hepatic coma this method of treatment was given. Blood values showed improvement and one patient recovered. It is postulated that unmodified blood transfusion has a place in treatment of liver failure particularly when associated with severe bleeding.

We wish to thank Dr. Morris C. Davis and Dr. J. L. Frew for permission to report Cases 1 and 3 respectively, and to Dr. J. A. Forbes for permission to report Cases 2 and 4.

Survey of Influenza Antibody in England by the Strain-specific Complement-fixation Test

MARGUERITE S. PEREIRA,* M.D.; PRATIMA CHAKRAVERTY,* B.SC.

T. M. POLLOCK,† M.B., M.R.C.P.GLASG.; J. G. POPE,† B.SC.

Brit. med. J., 1967, 4, 80-82

The susceptibility of a community to current strains of influenza virus is an important factor in the development of epidemics of influenza. Predictions of the likelihood of such epidemics and therefore recommendations for the use of vaccines against influenza should be based on what is known of the susceptibility of the population at risk and on the identity of circulating virus strains.

The influenza antibody survey described here was made to estimate the susceptibility to influenza viruses of all age groups in populations in several areas of England.

The laboratory tests previously used to determine antibody to influenza have certain drawbacks. Thus the haemagglutination inhibition test is sometimes difficult to interpret, since virus strains vary in their avidity for antibody and in their sensitivity to nonspecific inhibitors present in serum. Also the serum neutralization test in tissue culture is laborious and expensive.

By contrast the complement-fixation test is simple, and, as a microtest, economical in reagents. This test may be done by using as antigen either the type-specific S antigen or the subtype or strain-specific V antigen (Lief and Henle, 1956). The former is excellent for the diagnosis of acute influenzal illness, but because the antibody titre declines soon after infection it cannot be used to detect residual antibody. In addition to this limitation the soluble antigen is common to all influenza A viruses and will not react solely with influenza A₂ antibody.

By the development of the V antigen, strain-specific reactions were obtained in the complement-fixation test. Henle *et al.* (1958) demonstrated the value of this test for the antigenic analysis of influenza virus and showed also that antibody detected with the V antigen would persist for several years after infection. It seemed likely that this would indicate the proportion of a population which had already experienced influenza A₂ virus infection. The strain-specific complement-fixation test was therefore employed in this investigation.

Materials and Methods

Public health laboratories in five different locations in England sent samples of serum each week to the Virus Reference Laboratory during the period October 1965 to May 1966. These samples were selected by the sending laboratory from

the number submitted for various routine tests, the majority being for the estimation of antistreptolysin O titres or for Wassermann reactions. Sera from patients with acute respiratory illness were excluded. From October 1965 to January 1966 a first series of 729 sera were examined, and from January to May 1966 a second series of 1,054 sera.

Virus Strains.—In the first series sera were tested against a single V antigen prepared with influenza A₂/England/7/65 virus. For the second series three V antigens were prepared with the influenza A₂/Singapore/1/57, A₂/England/129/66, and B/England/5/66 viruses.

Antigens.—These were prepared by the methods of Lief and Henle (1956). Allantoic fluids were harvested from eggs inoculated 48 hours previously with the strains of influenza virus. The virus harvests were adsorbed to fowl cells at 0° C., followed by elution into small volumes of phosphate-buffered saline at pH 7.2 over a period of three to four hours. This cycle was repeated two or three times. The final eluates were then tested quantitatively for specific complement fixation by the chessboard method against a homologous antiserum prepared in ferrets and against an S specific antiserum prepared in guinea-pigs. The dilution of each antigen for use was taken to be that which fixed complement with the highest dilution of homologous ferret antiserum. This varied between 1/4 and 1/32. If there was fixation of complement with the S specific antiserum, further adsorption-elution cycles were done.

Complement-fixation Test.—The method was described by Pereira *et al.* (1964). It used 0.025 ml. unit volumes of the reagents in W.H.O. plastic plates and overnight fixation at +4° C. Sera were diluted in fourfold steps and mixed with the optimal dilution of the appropriate V antigen. Titres were recorded as the reciprocal of the highest serum dilution producing 50% fixation with the antigen.

Results

There was no indication of any appreciable difference in the results of tests on the sera from the different laboratories. In the analysis all the results have therefore been combined.

FIG. 1

FIG. 2

FIG. 3

FIG. 1.—Percentage of individuals with antibody to A₁/65 V antigen by age groups—all areas. October 1965 to January 1966. FIG. 2.—Percentage of individuals with antibody to A₂/England/66 by age groups—all areas. January to May 1966. FIG. 3.—Percentage of individuals with antibody to A₁/Singapore/57 by age groups—all areas. January to May 1966.

As shown in Tables I-III and in Figs. 1-3, a substantial proportion of sera from each age group contained antibody to each of the influenza A antigens. Antibody to the earliest strain, A₂/Singapore/1/57, was found most often. In persons aged 5-24 years few were without demonstrable antibody, and their sera included the greatest number with high titres against all the strains tested.

The antibody titres to each of the two A antigens in sera from 49 children under 5 years of age are shown in Fig. 4. Despite the antigenic shift of the influenza A strains since 1957 considerable crossing was found and antibody could be demonstrated in most instances against both variants. In the majority the titres were higher against the more recent strain.

50+	155 (55%)	36	11	35	14	18	5	5	279

In Table IV and Fig. 5 the presence of antibody against influenza B is shown to be relatively infrequent in sera from preschool children, but this incidence has increased sharply in the older children, reaching a peak among the young adults. The outbreaks of influenza B infection which occurred in many schools throughout the country in the early months of 1966 may have had a considerable influence on the formation of this pattern.

Discussion

Though the presence or absence of immunity to the current virus strains is a principal influence in the development of epidemics, there have been few attempts in England to assess

FIG. 4.—Antibody titres to A₂/57 and A₂/66 in individual children under 5 years.

FIG. 5.—Percentage of individuals with antibody to B/England/66 by age groups—all areas. January to May 1966.

the prevalence of immunity in the population by a survey of the influenza antibody titres over a wide range of age groups. In the present investigation these titres have been estimated in samples of serum from a large number of individuals of various ages in five areas of England.

More than 1,700 sera were tested, but the numbers of samples from most of the age groups were rather limited. A more selective investigation in additional areas would be necessary to confirm that the results obtained were truly representative of the titres in the general population. However, the results give a general indication of the proportion of persons with antibody in many areas in England.

The strain-specific complement-fixation test was found in practice to be very suitable for a survey of this kind, since it is simple and quick with a clearly recognizable end-point.

A previous investigation (to be published) showed that infection with influenza A₂ virus was followed by the production of antibody which could be detected equally well by the haemagglutination inhibition, serum neutralization, and strain-specific complement-fixation test and which persisted for at least nine years. In a few instances the complement-fixing and haemagglutination-inhibiting antibody had declined to a low titre by this time and occasionally even became undetectable, whereas neutralizing antibody could be demonstrated convincingly on all occasions. On this basis the results obtained by the present complement-fixation tests must be regarded as providing a modest estimate of the proportion of the population that possess antibody.

If, as seems probable, the presence of circulating antibody is accepted as indicating some degree of resistance to influenza, the findings clearly indicate that a substantial proportion of each age group in England is protected against the current strains of influenza virus. It follows, therefore, that until the antigenicity of the influenza strains is altered a widespread epidemic of influenza is unlikely in England.

The investigation demonstrated the heterogeneity of antibody to the influenza A₂ strains because antibody to one strain may

appear after infection with another. This is evident from the findings in children under 5 years old. In this group most of those with antibody to the A₂/England/129/66 strain also had antibody to the A₂/Singapore/1/57 strain, though the children could not have been infected with the A₂/Singapore/1/57 strain, because it had disappeared from England before many of them were born; moreover, most of them were too old for maternal antibody to the A₂/Singapore/1/57 strain to have persisted.

Summary

To obtain information on the susceptibility of communities to influenza-viruses serum samples from 1,783 persons of all ages living in five different areas of England were examined. Strain-specific complement-fixation tests for antibody to influenza viruses were used.

The results indicated that antibody to both early and late antigenic variants of influenza A₂ virus and to influenza B virus is widespread in all age groups. An epidemic due to the current strains is unlikely.

The strain-specific complement-fixation test was found to be highly suitable for this type of investigation.

We are grateful to Drs. B. Moore, C. E. D. Taylor, J. O'H. Tobin, and J. E. M. Whitehead, from the public health laboratories of Exeter, London, Manchester, and Coventry respectively, for sending us serum samples, and to Dr. T. Skeoch and Mr. H. Bell, of the Central Clinical Laboratory, Middlesbrough, for their help. We would like to thank two visiting workers from New Zealand, Dr. Jack Burton and Miss Marjorie Bennett, for their part in this investigation.

Antibodies in Children's Sera for Serologically Different Recently Isolated Strains of Influenza Viruses A₂ and B

G. C. SCHILD,* B.SC., PH.D.; C. H. STUART-HARRIS,† C.B.E., M.D., F.R.C.P.

Brit. med. J., 1967, 4, 82-84

The natural antigenic variation of the influenza viruses and its probable significance in relation to the sequence of epidemics and pandemics of human influenza is well known. In the case of the influenza A, A₁, and A₂ viruses the variation from one major antigenic form to another has occurred every ten or more years, but in between these happenings there have been minor variations with a progressive deviation from the prototype. In the case of the influenza B viruses it has not proved possible to group strains into families arranged in a chronological sequence of occurrence as with influenza A viruses, and the variation appears to have been relatively haphazard. The serological impact of the various races of both influenza A and B on the population has been studied by many workers. Davenport *et al.* (1953) were the first to show that different age-cohorts of the population exhibit different serological spectra against the major influenza A virus families. They attributed their findings to a dominating influence on the

immunological mechanism of childhood infection by the particular virus serotype then prevalent. Reinforcement of this antibody production by subsequent exposure to other serotypes occurs during adult life. Their doctrine of "original antigenic sin" or serological recapitulation of childhood antibodies has received support from numerous observations, including those derived from prospective studies on the same persons (Schild and Stuart-Harris, 1965).

The serological effects on man of minor antigenic variations occurring in interpandemic periods have, however, received little attention. Zhdanov (1967) has attempted to predict the occurrence of epidemics by examining sera with different serotypes represented by viruses isolated recently and from less recent epidemics. In such work children's sera are likely to yield more definitive information than those of adults because of the relatively specific character of the antibody response in childhood. The success of the Russian method in predicting the 1965 epidemic of A₂ and the 1967 outbreak of B influenza (Zhdanov *et al.*, 1966; Zhdanov, 1967) indicates that it is

† Department of Medicine, University of Sheffield.

worthy of wider exploration. Experience over prolonged periods of time will probably be necessary to assess its value. A start has been made on this in Sheffield by examining sera from children with recently isolated and serologically variant strains of influenza A₂ and B. The sera were collected at intervals from May 1965 onwards, and the period of study preceded and followed the mixed A₂ and B influenza epidemic of January to March 1966.

Materials and Methods

Sera were obtained from the laboratories at the Children's and Royal Hospitals in Sheffield, either from patients in the wards or from specimens from children living in the Sheffield hospital region, and submitted for antistreptolysin O titres or blood-grouping. With the consent of their parents, 30 sera were obtained from healthy children attending a welfare clinic in the West Riding. Sera were stored frozen at -20°C . in screw-capped bottles.

Virus Strains.—The A₂ viruses were the prototype 1957 strain A₂/Singapore/1/57, the A₂/England/12/64 representative of the variants occurring in 1964–6 (Pereira *et al.*, 1964), and A₂/Czechoslovakia/1/66 isolated in December 1966 and kindly supplied by Dr. H. G. Pereira, of the World Influenza Centre in London. The influenza B viruses were B/Lee/1940; B/England/939/59, B/England/101/62, B/Taiwan/4/62, and B/England/13/65. They were received from Dr. D. Hobson, of the University of Liverpool. B/Sheffield/66 was recovered in Sheffield in May 1966 from a patient with influenza. Pools of viruses were made by allantoic inoculation of 10-day embryonated eggs from stock cultures diluted 10^{-3} to 10^{-4} . After incubation at 35°C . for 48 hours the allantoic fluids were harvested, pooled, and stored frozen at -70°C .

Haemagglutination-inhibition Tests.—These were carried out in perspex trays by conventional methods (W.H.O., 1953), using 8 haemagglutinating units of virus and twofold serum

dilutions. All sera were treated before test to remove non-specific serum inhibitors by incubation overnight at 37°C . with 5 vols. of cholera filtrate (N.V. Phillips Roxane or Burroughs Wellcome Ltd.). They were subsequently heated at 56°C . for one hour to destroy the receptor-destroying enzyme.

Results

The ages of the children from whom the specimens were received varied from 6 months to 11 years at the time of collection. The serum collections were made in three periods—May to October 1965, January to March 1966, and October 1966 to February 1967. Not all the sera were tested against all the viruses, because of the actual volume of available serum. Figs. 1 to 7 show the proportion with antibodies for the appropriate viruses in each of these three serum collections. They represent at three titre levels the proportions with antibodies during and after the epidemic period (A₂ and B) of 1966. Though the serum specimens came from different children in each of the three periods of time, the figures for each period show the percentage of sera with positive haemagglutination-inhibition at 1 in 12, 1 in 48, and 1 in 192 dilutions. In each period of time the results from the children are shown at three separate ages of 6 months to 3 years, 3 to 6 years, and 6 to

FIGS. 1-3.—Percentage of children of various ages with haemagglutination-inhibition antibody at the stated titre to influenza A₂ virus strains.

* Range of birth dates.

A₂ Virus Antibodies

Table II and Figs. 1 to 3 show respectively the proportion of children with antibodies and the antibody distributions for the A₂ strains recovered in 1957, 1964, and 1966 and indicate definite differences in the results with the various viruses. Against the prototype A₂ virus shown in Fig. 1 there were relatively few differences between the various serum collections. The oldest children in each group who were alive during the earliest epidemics of the A₂ era in 1957 and 1959 show the greatest proportion of positive results (60 to 70%) and the greatest number with high-titred sera (10 to 20%). Relatively few sera from the youngest children born from 1962 onwards gave positive results with the Singapore virus, and all of the sera from those born since October 1963 were negative. The 1966 epidemic appeared to have had little effect on the titre distributions except that the proportion of sera positive at a 1 in 48 dilution was greater in the most recent than in the earlier collections.

TABLE II.—Antibodies to Influenza A₂ Viruses

Virus Strain	Serum Collections and No.	No. and Proportion of Sera Inhibitory at 1 in 12 Dilution or Higher					
		6 Months–3 Years		3–6 Years		6–11 Years	
		No.	%	No.	%	No.	%
A ₂ /Sing./57	May–Oct. 1965 (180)	7/45	16	30/70	43	35/65	46
	Jan.–Mar. 1966 (79)	2/16	12	13/34	38	19/29	66
	Oct. 1966–Feb. 1967 (65)	0/14	0	13/25	52	20/26	77
A ₂ /Eng./64	May–Oct. 1965 (180)	31/45	69	61/70	87	62/65	95
	Jan.–Mar. 1966 (60)	9/13	70	21/23	96	21/24	87
	Oct. 1966–Feb. 1967 (65)	11/14	78	23/25	92	25/26	96
A ₂ /Czech/66	May–Oct. 1965 (120)	1/30	3	11/55	20	9/35	26
	Jan.–Mar. 1966 (80)	1/15	7	21/35	60	21/30	70
	Oct. 1966–Feb. 1967 (65)	2/14	14	16/25	64	19/26	73

Antibodies against the A₂/64 virus (Fig. 2) were present in a higher proportion of sera in all three periods and at higher dilutions than with the A₂/57 virus. Indeed, the sera were so consistently inhibitory at 1 in 12 in all three collections that it is probable that A₂/64 virus is more avid for antibody than A₂/57. The results obtained by Dr. H. G. Pereira with convalescent ferret sera (Table III) did not, however, suggest the existence of an undue avidity of the A₂/64 virus, and the human results could also be explained on the basis of the cross-relationship of A₂/64 with the A₂/57 and A₂/66 viruses, together with the effects of the 1964 and 1966 epidemics. Thus 85% of the sera from the oldest children (6 to 11 years of age) exhibited antibodies for A₂/64 virus at 1 in 192 dilution in the 1966–7 collection; 50% of sera collected during January to March 1966 and only 25% of the 1965 sera were positive at 1 in 192. An increase of high-titred sera against A₂/64 virus also occurred in the groups of children under 3 years of age between the collection of sera early and later in 1966. These results probably indicate the effect of the outbreak of influenza in that year.

TABLE III.—Haemagglutination-inhibition Tests for Influenza A₂ Viruses with Immune Ferret Sera

Virus Strains	Sera		
	A ₂ /Singapore/1/57	A ₂ /England/12/64	A ₂ /England/1/66
A ₂ /Singapore/1/57 ..	2,560	160	160
A ₂ /England/12/64 ..	320	3,840	2,560
A ₂ /England/1/66 ..	240	960	1,920
A ₂ /Czechoslovakia/1/66	240	960	1,920

The results with the A₂/Czech/1/66 virus (Fig. 3) contrast with both the other A₂ viruses in that only a low percentage of the sera collected before January 1966 inhibited the virus. Even among the sera from the oldest children from the 1965 collection only 25% exhibited antibody demonstrable at 1 in 12 dilution, compared with 70% positive at the same dilution in both collections of sera from 1966. This result was surprising in that tests with convalescent ferret sera (Table III) showed only slight antigenic differences between A₂/England/12/64 and A₂/Czech/1/66 viruses. Nor did they suggest that the latter strain was significantly non-avid in the haemagglutination-inhibition test. In addition, the titres obtained with the ferret antisera show that A₂/Czech/66 is serologically closely related to an A₂ virus (A₂/England/1/66) isolated in Great Britain during the same year.

Influenza B Viruses

Antibodies were present in children's sera against each of the four B viruses isolated in England from 1959 to 1966 (Table IV), though the proportions and titres varied at different ages and in the different serum collections. Few sera contained demonstrable antibodies against the B/Lee/1940 and B/Taiwan/4/62 strains. Those which did so react with these viruses were almost invariably from the oldest children among the several groups in whom 10 to 30% were positive at 1 in 12. Such sera usually also possessed high antibody titres to the other influenza B strains, and particularly to B/England/13/65, thus suggesting that the antibodies to the Lee and Taiwan viruses were heterotypic and resulted from infection by the other B viruses.

Table IV indeed suggests that antibody orientated to B/Taiwan/62 might result from infection by the 1965 B viruses, for sera from ferrets convalescent from infection by the latter reacted also with the Taiwan strain. Similarly, cross-reactions between B/England/59 and Lee ferret antisera, also shown in Table IV, would explain the presence of antibodies against the Lee virus in the sera from children exposed to infection in 1959. In regard to B/England/65 and B/England/66 viruses close serological resemblances were found by Dr. H. G. Pereira (personal communication). These results are borne out by the titres obtained in our own laboratory (Table IV).

TABLE IV.—Serological Relation Between Influenza B Virus Strains in Haemagglutination-inhibition Tests with Immune Ferret Sera

Virus Strains	Ferret Sera			
	B/Lee/1940	B/England/939/59	B/Taiwan/4/62	B/England/5/65
B/Lee/1940	384	192	<12	NT
B/England/939/59 ..	<12	1,536	12	"
B/Taiwan/4/62 ..	<12	<12	192	"
B/England/101/62 ..	<12	192	<12	"
B/England/5/65 ..	NT	NT	NT	1,280
B/England/13/65 ..	<12	48	48	NT
B/Sheffield/66 ..	<12	24	12	960

Table V and Figs. 4 to 7 give the human serological results with the viruses isolated in 1959, 1962, 1965, and 1966, all of which show in varying degree the effect of the B outbreak in 1966. The fact that the older children, aged 6 to 11 years, exhibited higher titres than the infants in each group of sera is best explained by the repetitive effect of infection during the B epidemics in 1959 and 1962 on antibodies acquired before that date. The virus recovered in 1959 (Fig. 4) thus shows

the effect of the 1966 epidemic in that an increased proportion of sera was positive in all three dilutions in the serum collections from 1966 compared with that from 1965. The older children exhibited both an increased proportion of sera positive at 1 in 12 in the latest compared with the earliest collection (from 80% in 1965 to 95% in 1966) and an increased number with higher titres.

TABLE V.—Antibodies to Influenza B Viruses

Virus Strain	Serum Collections and No.	No. and Proportion of Sera Inhibitory at 1 in 12 Dilution or Higher					
		6 Months–3 Years		3–6 Years		6–11 Years	
		No.	%	No.	%	No.	%
B/Eng./59	May–Oct. 1965 (120)	3/30	10	11/55	20	27/35	77
	Jan.–Mar. 1966 (85)	8/16	50	29/39	73	28/30	93
	Oct. 1966–Feb. 1967 (90)	7/18	40	23/38	60	32/34	94
J/Eng./62	May–Oct. 1965 (80)	4/17	24	13/35	37	24/28	86
	Jan.–Mar. 1966 (110)	17/25	68	42/50	84	34/35	97
	Oct. 1966–Feb. 1967 (80)	6/18	33	19/33	58	24/29	83
B/Eng./65	May–Oct. 1965 (120)	0/30	0	16/55	29	16/35	46
	Jan.–Mar. 1966 (110)	10/25	40	28/50	56	27/35	77
	Oct. 1966–Feb. 1967 (90)	11/18	60	33/38	87	33/34	97
B/Sheff./66	May–Oct. 1965 (80)	1/17	8	5/35	14	8/28	28
	Jan.–Mar. 1966 (110)	7/25	28	20/50	40	15/35	43
	Oct. 1966–Feb. 1967 (80)	6/18	33	11/33	33	12/29	40

The pattern of antibodies against the B/England/62 virus (Fig. 5) was not greatly different from that obtained with the B/59 virus, as might be expected from the results with ferret antisera shown in Table IV. With the B/England/65 virus (Fig. 6) antibodies were not found in sera from the youngest children collected in 1965 but were present in 40% of sera from those aged less than 3 years collected in January to March 1966. Of the sera from the youngest children collected in 1966–7, 60% were positive at 1 in 12 and 30% at 1 in 48. The 1965 virus was thus inhibited by sera from the oldest children in all three collections, but a rise in both the proportion of inhibitory sera and in the number with strongly inhibitory properties occurred during 1966. The results with this virus are compatible with the view that the 1966 outbreak was associated with infection by a strain resembling B/England/65, as was indicated also by the results with ferret antisera (Table IV).

However, the B virus recovered in Sheffield in 1966, which yielded results with ferret sera similar to those with both 1965 and other 1966 viruses, gave different results with the children's sera (Fig. 7). In the sera from 1965 28% of the oldest and less than 10% of the youngest children were inhibitory at 1 in 12. Sera positive at 1 in 12 dilution formed from 30 to 40% at all ages of those collected during 1966. The 1966 outbreak thus appeared to have left the majority (60%) of children, whose sera were collected from October 1966 onwards, with no antibodies at all to this virus (Table V). The youngest children in this group also exhibited an almost total lack of antibodies at 1 in 48 or higher, as in the case of the sera from children from 6 months to 6 years of age collected in 1965.

Discussion

The purpose of this study was twofold. The first query was whether children's sera can be used to detect antigenic differences between recently isolated but serologically distinct virus strains. The results abundantly support the view that this is so. Indeed, children's sera appear to detect antigenic differences even more specifically than do sera from convalescent ferrets. The second purpose was to obtain baseline data concerning

the effect of an outbreak of influenza on the distribution of antibodies in children of different ages. Such data might enable one to predict the likelihood of an outbreak. So far as the A₂ viruses are concerned, A₂/England/64 was inhibited by a high proportion of sera collected before the 1966 outbreak, and therefore no indication would have been obtained with this strain of the imminence of an A₂ outbreak. Had the A₂/66 variant been available, however, it would have revealed a low percentage (from 4 to 26) of children of all ages with antibodies in the pre-epidemic period. Thus the likelihood of an outbreak could have been foreseen, but probably only retrospectively, by using the epidemic strain.

In the case of the B viruses the data show once again that there was a deficiency of antibodies in pre-epidemic sera against the virus which caused an outbreak in 1966. Yet, in spite of the known occurrence of localized outbreaks in the January-to-March period of that year, the 1965 B virus showed a similar deficiency of antibodies in the youngest children. Even in the case of children aged 3 to 6 years, only 29% exhibited antibody to the 1965 virus strain. On these grounds, therefore, the likelihood of a recurrence of infection by the 1965 virus or a related strain such as that actually experienced in 1966 might have been considered probable.

It seems clear that further experience with sera from the youngest segment of the population other than those with maternal antibodies may give an indication of the likelihood of an outbreak if a very recently isolated antigenic variant is available. Much more experience will be necessary, however, before this method of prediction can be properly evaluated. For instance, a general lack of antibody to B/Taiwan/4/62 virus existed in the children's sera. This strain, isolated in 1962, was found at that time to be serologically distinct from previously known influenza B strains (Green *et al.*, 1964). Yet it has never again been identified in an epidemic of influenza, a fact which indicates that not all antigenic variants of the influenza viruses are successful pathogenic agents even in the absence of serological immunity. Therefore the recovery of a new variant may not predicate the immediate likelihood of an outbreak of that virus.

Summary

A survey has been carried out on the incidence of haemagglutination-inhibiting antibody to influenza A₂ and B virus strains isolated between 1957 and 1966 in sera collected from children aged 6 months to 11 years. Evidence of recent infection in the community with the various test viruses was indicated by changes in the frequency of occurrence of antibody in sera collected at different periods of time during the study. Serological differences were demonstrated between influenza virus strains even when the latter were closely related in tests with immune animal sera. The study provides baseline information on the effect of outbreaks of influenza on the distribution of antibodies in children's sera and raises the possibility of using such data in the prediction of future influenza epidemics.

We wish to thank Dr. H. G. Pereira, of the World Influenza Centre, London, for the provision of virus strains and immune animal sera and for helpful discussion. Dr. D. Hobson, of the University of Liverpool, kindly provided other virus strains. We are grateful for the excellent technical assistance of Miss K. Cullen and Miss J. A. Waite.

Measurement of Blood Loss by Means of a Whole-body Counter

J. M. HOLT,* M.D., M.R.C.P.; F. G. H. MAYET,*† M.D.; G. T. WARNER*;
S. T. CALLENDER,* M.D., F.R.C.P.

Brit. med. J., 1967, 4, 86-88

In the investigation of patients with hypochromic anaemia the assessment of the part played by gastrointestinal or menstrual blood loss is often extremely difficult. This paper describes a method for the measurement of blood loss over periods of up to three months by means of ^{59}Fe and the simple whole-body counter recently designed in this department (Callender *et al.*, 1966). The principles involved are that 7 to 10 days after the administration of ^{59}Fe all or most of the dose will be incorporated into circulating red cells. In normal males and postmenopausal females the whole-body radioactivity will remain stable and any loss in total body radioactivity must represent loss of blood. The technique was evaluated by studying patients with polycythaemia from whom known quantities of blood were removed by venesection. Its clinical use is illustrated by studies of five patients with hypochromic anaemia.

Methods

The design of the whole-body counter and its uses in measuring absorption have been described in detail elsewhere (Warner and Oliver, 1966; Callender *et al.*, 1966). The majority of subjects studied were given an intravenous tracer dose of ^{59}Fe ferric citrate with 1.5 to 1.0 μCi activity; subjects in whom additional information on the ability to absorb iron was required were given an oral dose of 5 mg. of ferrous iron labelled with approximately 5 μCi ^{59}Fe .

Patients Studied.—Four patients who had recovered from a myocardial infarct agreed to act as control subjects. All were outpatients and none was receiving anticoagulant drugs. They were studied over a period of three months in order to measure the normal daily iron loss as blood and to assess the week-to-week variation of the whole-body counter. Twelve patients with polycythaemia who required therapeutic venesection were studied; three were postmenopausal females and nine were males. Ten had polycythaemia vera and two had secondary polycythaemia. Plasma iron disappearance curves were plotted and used for estimation of blood volume. Seven to 10 days after the injection of ^{59}Fe (day zero of the experiment) the whole-body radioactivity was measured. Thereafter venesections were carried out at varying intervals of a few hours to three weeks. The whole-body radioactivity was measured immediately before and after each venesection. Five patients with iron-deficiency anaemia in whom either gastrointestinal bleeding or excessive menstrual loss was suspected were investigated. The proportion of the oral dose retained at 10 days was a measure of iron absorption. Thereafter the total body activity was measured at intervals.

Calculation of Blood Loss.— L =Percentage loss of whole-body radioactivity between counts. BV =Blood volume in ml.

$$\text{Blood loss in ml.} = \frac{L}{100} \times BV$$

In control subjects and patients with iron-deficiency anaemia the blood volume was taken to be 65.6 ml./kg. body weight (Wasserman *et al.*, 1951). For the purpose of this calculation it was thought reasonable to assume that in polycythaemia and

iron-deficiency anaemia the red-cell utilization of ^{59}Fe could be taken as 100%. This was verified in a number of subjects. When 100% utilization was not expected—for example, in control subjects—the utilization was measured and the appropriate correction made.

Results

Control Subjects

The whole-body counts expressed as a percentage of the count on day zero were plotted against time in days (Fig. 1). The mean loss of ^{59}Fe per day was $0.031\% \pm 0.039\%$. The calculated blood loss per 100 days was 152, 155, 160, and 182 ml. respectively. After correction for the amount of blood removed for blood sampling the losses were 142, 105, 90, and 132 ml. (mean 117 ml.).

Patients with Polycythaemia

A total of 39 venesections were carried out in the 12 patients, and the calculated volume of blood lost on each occasion was compared with the known volume of blood removed by venesection. The difference, or error, was expressed as a percentage of the known volume removed. In 10 instances between 100 and 300 ml. of blood was removed; the mean error was -10% , the range -48% to $+63\%$, and the standard deviation of the errors $\pm 36\%$. On the other 29 occasions between 395 and 520 ml. of blood was removed; the mean error was -12% , the range -60% to $+50\%$, and the standard deviation of the errors $\pm 26\%$.

Venesections Carried Out Over Periods of up to 97 Days. The Known and Calculated Losses are Compared

Period of Study in Days	Blood Removed (ml.)	Calculated Blood Loss (ml.)	Difference (ml.)	Error (%)
1	688	586	-102	-15
1	715	662	-53	-7

The Table concerns the nine patients in whom blood was removed by repeated venesection, carried out at intervals during periods of from 1 to 97 days. The sum of the calculated blood losses in each case is compared with the total volume removed by venesection. In these calculations only the whole-body count before each venesection was used in order to simulate the situation in which a patient with continuous blood loss was having single whole-body counts at intervals. The mean error was -0.2% , the range -22% to $+23\%$, and the standard deviation of the errors $\pm 14\%$.

In order to demonstrate the relation between whole-body ^{59}Fe activity and blood loss the results from one patient are shown in Fig. 1, where the graph is compared with that from the control subjects.

* Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford.
† Present address: Department of Medicine, University of Natal, Durban.

Patients with Hypochromic Anaemia

The results are shown in Figs. 2-6, where whole-body counts expressed as a percentage of the whole-body count on day zero are plotted against time in days. The percentage absorption of the orally administered dose and the blood loss are recorded.

One patient had occult gastrointestinal bleeding from telangiectases due to scleroderma, and Fig. 2 shows how most of the bleeding occurred during the first 21 days of the study. In 15 weeks 1.8 litres of blood was lost, but as she can absorb oral iron well her haemoglobin can be maintained at a satisfactory level by continuous treatment.

The second patient had recurrent iron-deficiency anaemia. Her iron absorption was normal and her anaemia was attributed to menorrhagia. The magnitude of the bleeding was not, however, fully appreciated until this study showed a loss of 870 ml. during a single menstrual period. Hysterectomy was therefore advised. Fig. 3 shows that the operation was performed without much loss of blood and that thereafter there was no significant fall in whole-body radioactivity, confirming that menorrhagia was the sole cause of her anaemia.

The third patient was an 18-year-old boy who complained of increasing shortness of breath and cough with haemoptysis. He was found to have a severe hypochromic anaemia, and a chest radiograph showed diffuse opacities in both lower lobes. Fig. 4 shows that the whole-body radioactivity remained con-

stant despite a fall in haemoglobin, indicating that blood loss was not the cause of the anaemia. Later, iron-containing macrophages were found in the sputum and a diagnosis of idiopathic pulmonary haemosiderosis was made. Though blood was being lost from the circulation, it was being sequestered in the lung, thereby explaining why the whole-body radioactivity did not fall.

The fourth patient was a 16-year-old boy with the Ehlers-Danlos syndrome who had recurrent iron-deficiency anaemia. Fig. 5 shows that he lost 1.3 litres of blood in 92 days from the gastrointestinal tract, and though it was not practicable to measure absorption of iron he was able to maintain a satisfactory haemoglobin provided he took iron by mouth continuously.

The fifth patient was a 53-year-old man with ankylosing spondylitis who had had a recurrent iron-deficiency anaemia for 12 years. During the period of study (Fig. 6) he had been taking between 1 and 2 g. of paracetamol a day to control pain, and it seems likely that the gastrointestinal blood loss, which amounted to 1.2 litres in 105 days, was related to treatment.

Discussion

The method described here is sensitive enough to detect blood loss of the order of 100 to 300 ml. but with only limited

accuracy and reproducibility (mean error -10% , standard deviation $\pm 36\%$). Blood loss of the order of 400 to 500 ml. can be measured with greater reproducibility (-12% , $\pm 26\%$). However, blood loss of the order of 700 to 3,000 ml. computed from consecutive whole-body counts over periods of time ranging from 1 to 97 days can be measured with sufficient accuracy and reproducibility (-0.2% , $\pm 14\%$) to be of use in the quantitative assessment of blood loss in patients with hypochromic anaemia, over periods of up to three months.

Although a whole-body counter has previously been applied to clinical problems of blood loss (Price *et al.*, 1964), the technique has never been evaluated critically. Price *et al.* calculated menstrual blood loss against a direct measurement of the ^{59}Fe content of tampons in one case, and thought an error of 20–40 ml. in losses amounting to 33–59 ml. was likely. Nevertheless it is probably wrong to assume that blood loss occurring clinically can be measured with the same precision as was attained with venesection of patients with polycythaemia. Gastrointestinal or menstrual bleeding may occur erratically and lead to fluctuations in the red cell content of ^{59}Fe and blood volume, both of which cannot be corrected for.

By the above method we are unable to measure reliably blood loss of the order of 100 ml., and an accurate assessment of a single moderately heavy menstrual period is not possible. However, a more accurate measurement is possible if the patient is followed over three or four menstrual cycles.

The ease and simplicity of the technique described here is such that all the studies were carried out on subjects visiting

the department as outpatients. The technique is now available in this hospital as a diagnostic service and is being used to study the mechanism of anaemia in patients with hiatus hernia, ulcerative colitis, and Crohn's disease.

Summary

A method is described for the measurement of blood loss over periods of up to three months by means of ^{59}Fe and a whole-body counter. Patients with polycythaemia from whom known quantities of blood were removed by venesection were studied to evaluate this technique. The method is sensitive and accurate enough for clinical purposes, and blood loss of more than 700 ml. can be measured with reproducibility of $\pm 14\%$. To illustrate its application to clinical problems, studies of five cases of hypochromic anaemia are described.

We wish to thank Miss Marjorie Alcock for technical assistance. The work was in part supported by a grant from the Medical Research Council.

Effect of Transfusion Materials on Rouleaux Formation and Sedimentation Rate of Erythrocytes

A. J. SALSBUURY,* M.D.

Brit. med. J., 1967; **4**, 88–90

The range and variety of plasma expanders and plasma substitutes are constantly increasing, particularly in the case of dextran solutions (Mollison, 1967; *Brit. med. J.*, 1967). A relatively new dextran is dextran 110, which has a high molecular weight though lower than that of the longer-established dextran 150. Ricketts (1966) has investigated the properties of a modified dextran similar to dextran 110. He found that the effect of this dextran on the red-cell sedimentation rate was substantially less than that of dextran 150 and that red-cell aggregation in the rabbit was minimal. Rouleaux formation was found to interfere with cross-matching in only two out of nine patients who received modified dextran.

In view of these results, it was decided to undertake a series of investigations in vitro to determine the effect of dextran 110, dextran 150, Macrodex, a commercial plasma protein solution, and plasma itself upon red-cell rouleaux formation, blood typing, and cross-matching.

Methods and Results

In the experiments the following standard transfusion materials were compared: (1) reconstituted dried human plasma; (2) a commercial 4.3% plasma protein solution (Serological Products Ltd.); (3) 6% w/v Macrodex in normal saline (Pharmacia (Great Britain) Ltd.); (4) 6% w/v dextran

110 in normal saline (Fisons Pharmaceuticals Ltd.); (5) 6% w/v dextran 150 in normal saline (Fisons Pharmaceuticals Ltd.). As a control, tests were also set up with normal saline in place of one of the above substances. All samples of blood were taken from healthy human volunteers into Sequestrene (sodium edetate). The Westergren sedimentation rate of each sample was 2 mm. in the first hour. Three main sets of experiments were then performed.

Effect of Varying Concentrations of Transfusion Materials on the E.S.R.—The transfusion materials listed above were mixed with blood in dilutions of 1 in 10, 1 in 20, and 1 in 40 (Table I). Five different samples of blood were tested (Tests A–E). Citrate was added to each mixture and the samples were set up in Westergren tubes at room temperature, results being read at the end of one hour. The substitution of plasma or plasma protein solution for saline had no effect on the sedimentation rate (Table I). The substitution of dextran 150 markedly raised the E.S.R. The effect of dextran 110 was less pronounced, but still considerable, while that of Macrodex was moderate. The greater the concentration of Macrodex, dextran 110, or dextran 150, the greater their effect on the E.S.R. This increased effect, however, was much less pronounced with Macrodex than with dextran 110 or dextran 150.

Effect of Transfusion Materials and Anaemia on the E.S.R.—The concentration of transfusion material added to blood was kept constant at 1 in 10. Three different samples of blood were used (Tests I–III). The samples were adjusted by centrifugation and reconstitution of cells and plasma to give haemo-

* Department of Haematology, St. Bartholomew's Hospital, London E.C.1.

globin levels ranging between 30 and 110%, before any transfusion material was added. Westergren sedimentation rates were investigated as in the first set of experiments. The results (Table II) essentially resembled those of the first set of experiments. The sedimentation rate was unaffected by plasma or plasma-protein solution and only moderately affected by Macrodex, even in the specimens with the lowest haemoglobin concentrations. Nevertheless, dextran 110 and dextran 150 produced a striking increase in the E.S.R., which became more pronounced as the haemoglobin concentration in the blood specimen fell.

Effect of Transfusion Materials upon Cross-matching.—Mock saline cross-matching tests were set up in this experiment. Five samples of normal blood were made up as 5% red-cell suspensions in normal saline. Single drops of each suspension were placed in precipitin tubes. To each was added one drop of serum from the corresponding subject, containing a 1 in 10 dilution of the appropriate transfusion material. The tubes were incubated at 37° C. for two hours. At the end of this time any red-cell aggregation visible to the naked eye was noted and the results were read microscopically. No macroscopic red-cell aggregation or microscopical rouleaux formation was observed in the tubes containing saline, plasma, or plasma-protein solution. With Macrodex a fine granularity was visible

to the naked eye and some rouleaux formation was seen on microscopy (Fig. 1). Both dextran 110 and dextran 150 produced a coarse granulation, macroscopically resembling agglutination. Under the microscope, aggregation of red cells into large masses almost impossible to distinguish as rouleaux could be seen. This effect was only slightly less marked with dextran 110 (Fig. 2) than with dextran 150.

FIG. 1.—Rouleaux formation in a saline cross-match containing Macrodex.

FIG. 2.—Rouleaux formation in a saline cross-match containing dextran 110.

Discussion

The in vitro addition of plasma or plasma-protein solution to blood was found to have a virtually negligible effect upon rouleaux formation and the erythrocyte sedimentation rate. On the other hand, all dextrans tested under these conditions produced some rouleaux formation and an increase in sedimentation rate. Of the dextrans, Macrodex exerted the least effect. Rouleaux formation was slight and the increase in sedimentation rate only moderate. The rouleaux formation was readily recognized microscopically and was unlikely to lead to any difficulty in blood grouping and cross-matching. These findings were in agreement with previous reports on the effect of Macrodex upon blood typing and cross-matching (Turner *et al.*, 1949; Bloom, 1951; Roche *et al.*, 1952; Bowman, 1953; Arndt-Hanser, 1956; Pettenkofer, 1959; Haynes, 1960).

Surprisingly, dextran 110 produced rouleaux formation as readily as dextran 150. The degree of rouleaux formation was

severe enough to cause considerable difficulty in blood grouping and saline cross-matching. There are at present few published accounts dealing with this aspect of dextran 110. Ricketts (1966) found rouleaux formation a hindrance to satisfactory saline cross-matching in only two cases, and then with serum concentrations of modified dextran considerably higher than in the present investigation. Though Ricketts found a moderate increase in E.S.R. with modified dextran in experiments in vitro, this could not be compared directly with the marked increase noted here, since Ricketts used the Wintrobe method for estimating the E.S.R.

There is a critical level of molecular weight so far as rouleaux formation by dextrans is concerned (Thorsén and Hint, 1950). Dextrans with an average molecular weight below 60,000 cause no increase in sedimentation rate. As the molecular weight increases above 60,000, red-cell rouleaux formation appears and the sedimentation rate rises progressively.

Macrodex has an average molecular weight of about 70,000. About 10% of the preparation has a mean molecular weight of 108,000 and 9% of 25,800 (Kjellman, 1965; Rousell, 1966; Nilsson, 1967). Hence on average Macrodex is only slightly above the critical molecular weight. Dextran 110 has an average molecular weight of about 110,000. Ten per cent. of the preparation has a mean molecular weight of 194,000, and 8% of 35,000 (Nilsson, 1967). This is reflected in an increased tendency to cause rouleaux formation and a rise in the erythrocyte sedimentation rate.

Thus from the point of view of effective blood grouping and cross-matching it would seem essential to take blood from a patient for these purposes *before* administration of dextran 110 or dextran 150. If immediate transfusion before withdrawal of blood is required Macrodex will cause little interference, and plasma or plasma-protein solution no interference, with blood grouping and cross-matching.

Summary

Plasma, plasma-protein solution, Macrodex, dextran 110, and dextran 150 were compared for their effect upon red-cell rouleaux formation and erythrocyte sedimentation rate in a series of in vitro experiments.

Plasma and plasma-protein solution do not produce rouleaux formation and have no effect upon the sedimentation rate. Macrodex, in concentrations likely to be found in plasma, does not cause marked rouleaux formation. Therefore administration of these substances before the taking of blood is unlikely to lead to any difficulty in blood grouping and cross-matching.

In contrast, both dextran 110 and dextran 150 produce marked rouleaux formation and a considerable rise in the E.S.R. They are likely to interfere with blood grouping and cross-matching, and should be given to a patient only *after* blood has been withdrawn.

Many thanks are due to Professor D. L. Mollin for the great interest that he has shown in this paper and for his many helpful comments.

Paget's Disease: a Family with Six Cases

J. VERRIER JONES,* B.M., M.R.C.P.; MERVYN F. REED,† M.B., CH.B.

Brit. med. J., 1967, 4, 90-91

Although McKusick (1966) states that 52 families have been reported in which more than one member suffered from Paget's disease, it is a striking fact that there have been only three reports of familial Paget's disease occurring in Great Britain. Kilner (1904) recorded an affected brother and sister, and Smith (1905) an affected father and son. Rast and Weber (1937) described the cases of three affected sisters. The literature on familial Paget's disease has been fully reviewed by Ravault, Lejeune, Robert, and Maitrepierre (1963) and by McKusick (1966). Records have been published of one family with four confirmed and two probable cases (Ravault *et al.*, 1963), two families with six cases (Hanke, 1935; Dickson, Camp, and Ghormley, 1945), and one family with five cases (van Bogaert, 1933). The remainder of the reports are of smaller families. McKusick (1966) draws attention to the difficulty of studying the familial incidence of a disease which is often asymptomatic, and suggests that "it may be that a study of families using alkaline phosphatase determinations as a screening procedure would be productive."

The purpose of this paper is to put on record an English family in which six cases of Paget's disease have occurred in three generations, and in which nine unaffected members of

the family have been studied. Radiological investigations and alkaline phosphatase estimations have been made in 13 members of the family.

The Family

Details of the family are set out in the genealogical diagram and in the Table. Thirteen members of the family were visited. All were examined clinically, x-ray films of the pelvis and tibiae were taken, and the alkaline phosphatase was estimated. In the case of two members of the family who were dead (I 1 and II 3) it was possible to make a diagnosis of Paget's disease with reasonable certainty from the evidence given by the rest of the family. Four living members of the family had clinical Paget's disease (details are given in the Table), and in all of these the alkaline phosphatase was raised. Nine members, ranging in age from 81 to 17 years, had no clinical evidence of Paget's disease, and their bone radiographs and alkaline phosphatase were normal. The age of onset of Paget's disease in this family seems to be in the decade 40 to 50. Three of the unaffected members are in this age group, and are therefore likely to remain unaffected. Of the remaining six (aged 17 to 29) several are likely to develop the disease in later life. This study suggests that there are no early x-ray changes or abnor-

malities of alkaline phosphatase on which it is possible to predict the subsequent development of Paget's disease.

Discussion

Paget (1889), in his original description of osteitis deformans, wrote: "I have tried in vain to trace any hereditary tendency

Genealogical diagram. Details of individual members are shown in the Table.

Details of Family

- I 1. Very bowed legs; had coffin made specially.
- II 1. Aged 81. Normal. Alkaline phosphatase (A.P.) 9.7 K.A. units/100 ml.
2. Aged 80. Paget's disease left tibia and pelvis. A.P. 26.
3. Legs deformed. Died 1937.
4. Aged 66 at death (1960). No evidence of Paget's disease.
- III 1. Aged 56. Paget's disease right tibia and pelvis. A.P. 36.
2. Aged 54. Paget's disease pelvis, both femora, both tibia. A.P. 54.
3. Aged 53. Normal. A.P. 7.
4. Aged 52. Paget's disease of lumbar vertebrae and pelvis. A.P. 76.
5. Aged 40. Normal. A.P. 6.
- IV 1. Died at age 16 (1957)—accident.
2. Aged 21. Normal. A.P. 14.
3. Aged 17. Normal. A.P. 7.
4. Aged 24. Normal. A.P. 10.
5. Aged 19. Normal. A.P. 6.
6. Aged 20. Not studied.
7. Aged 29. Normal. A.P. 11.
8. Aged 22. Normal. A.P. 7.
9. Aged 10. Not studied.
- V The members of this generation are all below the age of 10, and have not been studied.

to the disease. I have not found it twice in the same family." Rosenkrantz, Wolf, and Kaicher (1952), in a review of 111 cases, do not mention a familial form of the disease. Most of the previous reports of families with Paget's disease have been from France, Germany, or the U.S.A. The family reported here seems to be the largest family group reported in Great Britain.

All previous reports suggest that the pattern of inheritance is compatible with an autosomal dominant gene with incomplete penetrance, with the exception of Ashley Montagu (1949), who suggested that it was inherited as a sex-linked recessive. Our findings are consistent with an autosomal dominant inheritance.

Clinically the disease in the family studied seems limited to the tibiae, pelvis, and lumbar spine. No case involving the skull has been encountered. The cases are all reasonably benign, with only minor symptoms in most cases and no instance of cardiac failure. This is comparable with the case reports in the literature.

Summary

An English family is reported in which six cases of Paget's disease have occurred in three generations. Nine unaffected members of the family have also been studied. There is no evidence of radiological abnormality in the clinically unaffected members, and alkaline phosphatase levels are normal. The disease is mild (with onset of symptoms in the fifth decade), and appears to be inherited as an autosomal dominant.

We are grateful to Dr. E. Rhys Davies and to the radiology department, Bristol General Hospital, for radiological studies on most of these patients. It is a pleasure to acknowledge the assistance of the patients' general practitioners.

Preliminary Communications

Evidence for Autonomic Denervation in Familial Dysautonomia, the Riley-Day Syndrome

Brit. med. J., 1967, 4, 91-92

The clinical features and experimental findings in familial dysautonomia have been summarized by Riley (1957), Riley and Moore (1966), and Goodall *et al.* (1967). Vasomotor instability, poor muscular co-ordination, impairment of sweating lacrimation and temperature control, and defective taste all point to a widespread neurological disorder. The absence of a flare in response to intradermal histamine and the exaggerated response to infusions of methacholine or noradrenaline offer further evidence of faulty autonomic control, as does the potentiated miosis following instillation of methacholine drops into the conjunctival sac.

Pupil responses to sympathomimetic amines have recently been used in studies on surgically induced sympathetic denervation and to evaluate the mode of action of adrenergic blocking drugs, such as guanethidine (Sneddon and Turner, 1967). Smith, Dancis, and Breinin (1965) investigated some of the ocular responses to autonomic drugs in familial dysautonomia, and concluded that there was evidence of parasympathetic but not of sympathetic denervation. The pupil responses in a female patient aged 18 months with this condition, reported in detail elsewhere (Goodall *et al.*, 1967), are here described, the results extending and differing from previous accounts.

METHOD

The experimental procedure is that described by Sneddon and Turner (1967). The eyes of the patient, and of four control children taking no drugs and who were matched for

age and eye colour (dark brown), were photographed under standard lighting conditions. The nature of the procedure was fully explained to the parents of these children, and their permission was obtained in every case. A Nikon F single lens reflex camera was used, mounted on a movable stand with bellows attachment. The camera settings were fixed and the whole camera was moved for focusing, resulting in a constant magnification of $\times 2$ when the patient's pupils were in focus. Four photographs of each subject were taken within a 15-second interval every 10 minutes for 30 minutes after the instillation of one drop of the drug under investigation into the conjunctival sac. In the subsequent measurements of pupil size the negatives were projected on to a white screen at a final magnification of $\times 8$. Pupil diameters were measured as the transverse diameter of this image and mydriasis or miosis was expressed as the percentage increase or decrease in pupil diameter from control values determined before drug instillation.

The drugs used were eye-drops containing methacholine 2.5%, physostigmine 0.5%, phenylephrine 10%, or ephedrine 2%. The experiments were carried out over four weeks, a different drug being administered each week.

RESULTS

The results are shown in the Table. Methacholine and physostigmine produced a greater miosis in the patient than in the control subjects. The mydriasis produced by phenyl-

Percentage Miosis and Mydriasis at 30 Minutes After Administration of Drugs into the Conjunctival Sac of One Eye in Four Control Subjects and a Patient with Familial Dysautonomia. The Results are the Means of Four Readings From Each Subject

	% Miosis				% Mydriasis			
	Methacholine 2.5%		Physostigmine 0.5%		Phenylephrine 10%		Ephedrine 2%	
	Mean	S.E.	Mean	S.E.	Mean	S.E.	Mean	S.E.
Controls	0	0	44	7	25	4	33	5
Patient	39	5	72	7	61	2	0	0

ephrine was also much greater in the patient, but ephedrine, which produced a mydriasis in the controls, did not have a measurable effect in the patient.

DISCUSSION

The mydriatic action of sympathomimetic amines is less in subjects with dark irides than those with light irides (Obianwu and Rand, 1965). It is therefore important to match subjects for eye colour.

Methacholine acts directly on parasympathetic end-organ receptor sites. The exaggerated response to this drug in our patient is characteristic of denervation (Emmelin, 1961) and indicates that usually her pupil has little if any parasympathetic tone. When the anticholinesterase drug physostigmine is given it is apparent that the pupil also reacts to endogenously released

acetylcholine. Physostigmine prevents its breakdown, and the miosis following its administration is good evidence that acetylcholine is being synthesized in parasympathetic nerve endings, though the rate may be reduced or its release impaired. Unfortunately there is no parasympathomimetic drug available analogous to ephedrine on the sympathetic system which releases stored acetylcholine from nerve endings. These findings agree with those of other workers and indicate a partial parasympathetic denervation phenomenon.

The response to phenylephrine, a sympathomimetic drug acting directly on sympathetic end-organ receptor sites, has not previously been documented. Together with the response to ephedrine, which releases noradrenaline from granules in postganglionic sympathetic nerve endings, the responses are similar to those found in surgically induced Horner's syndrome and in chronic treatment with local guanethidine (Sneddon and Turner, 1967).

This is good evidence that the response in familial dysautonomia parallels sympathetic denervation produced artificially. Though this conclusion differs from other reports, it is in agreement with the increased sensitivity to noradrenaline infusion found in this condition (Smith and Dancis, 1964). The absence of ephedrine mydriasis indicates absent or reduced transmitter stores in the sympathetic nerve ending.

We did not use adrenaline eye-drops as absorption is unpredictable, nor cocaine, as it was thought undesirable to anaesthetize the eyes of control subjects of this age. This has been done in older children and a mydriasis reported (Smith *et al.*, 1965), but the degree of dilatation compared with control subjects was not stated.

SUMMARY

Denervation phenomena both in the sympathetic and in the parasympathetic control of pupil diameters are reported in a child with familial dysautonomia.

Exaggerated responses were demonstrated to parasympathetic and direct-acting sympathomimetic agents.

We thank Dr. Dennis Cottom for permission to study patients under his care at the Hospital for Sick Children, Great Ormond Street, London W.C.1.

Corrosive Damage to Stomach Simulating Carcinoma

Brit. med. J., 1967, 4, 93-94

Lesions of the stomach after the ingestion of corrosives are reported infrequently in the British surgical literature. Such lesions are apparently more common in the United States and Europe.

The case reported is of interest in that it has unusual features but at the same time illustrates some of the classical points found after corrosive injury. It is unusual in the diffuse nature of the gastric damage produced and the way in which it was treated. It shows, on the other hand, the following classical features: the history of mental disease, the sparing of the oesophagus, the ulceration, and the difficulty found in differentiating corrosion from carcinoma. The similarity between cancer and a corrosive lesion was here so striking that at operation a confident diagnosis of the linitis plastica type of carcinoma was made.

CASE REPORT

A 57-year-old carpenter was brought to the accident unit on 20 February 1965, having drunk a quarter of a pint (140 ml.) of yellow fluid from a bottle labelled "turpentine." This fluid was used as a soldering flux and was found to contain a high proportion of hydrochloric acid. The patient had been under the care of a psychiatrist for a depressive illness for one year. He had twice been admitted to a mental hospital for electric convulsion therapy, and was due for readmission on 21 February. After drinking the fluid he had vomited and become drowsy, and complained of pain in the abdomen. When examined in the accident unit he had hypotension, abdominal tenderness, and a blackened tongue. His blood pressure rapidly returned to normal. He was given sodium bicarbonate to

drink and was admitted. After a few days' observation, he was discharged to the mental hospital.

On 4 March he was again brought to the accident unit. He had vomited fresh blood twice during the previous six hours. His blood pressure was 110/90 mm. Hg, and there were no abnormal physical signs. On direct questioning he admitted having had indigestion for some weeks. Barium studies showed a small, aperistaltic, rapidly emptying stomach with a small ulcer on the lesser curve of the pyloric antrum, the appearances being consistent with a diffuse scirrhus carcinoma (Fig. 1). Surgical opinion was sought and a laparotomy was undertaken on 24 March. A thoracoabdominal incision was made through the bed of the seventh rib, dividing the diaphragm to the hiatus. The stomach appeared to be of a dark red colour, and its walls felt thick and of firm consistency. The whole organ was adherent to the neighbouring viscera. There were hard lymph nodes in the splenic hilum and in the gastrohepatic omentum. The liver and other viscera were normal. A confident diagnosis of carcinoma of the stomach was made and a total gastrectomy was decided on. The body and tail of the pancreas, spleen, and greater and lesser omenta were removed en bloc with the stomach. Reconstitution was made by a Roux-en-Y oesophagojejunostomy, and a jejunojejunostomy was performed distal to the anastomosis. A Ryle tube was left across the anastomosis and the pleural space was drained to an underwater seal. Recovery was uneventful and he was discharged 19 days after operation.

The pathologist's report on the excised stomach was as follows: "A subacute gastritis involving most of the stomach and characterized by ulcers with a floor of granulation tissue lacking the usual zone of necrosis seen in peptic ulceration (Fig. 2). Infiltration most marked in the mucosa and submucosa with lymphocytes, plasma cells, and eosinophils. Occasional small epithelioid cell and giant-cell granulomata, with giant cells in the superficial granulation tissue. Small cysts filled with fatty material and extensive endarteritis and endophlebitis fibrosa. Nonspecific catarrh in the lymph nodes." The pathologist was of the opinion that such a lesion could have been due to the consumption of corrosive material some weeks previously.

COMMENT

Many agents can cause corrosive gastritis. Hydrochloric acid is the commonest in England; usually it is found in soldering flux. Others are sulphuric and nitric acids, more rarely lysol and formaldehyde. The first case in the world literature was reported by Robert in 1828. His patient drank sulphuric acid. The case of a patient who drank formaldehyde was reported in Britain by Vinson and Harrington (1929).

Corrosives are drunk most commonly by people with mental disorders, as in this case. They may also be taken by mistake

FIG. 1.—Photograph showing steerhorn stomach and a lesser-curve ulcer at pyloric antrum.

FIG. 2.—Floor of ulcerated area to show granulation tissue heavily infiltrated with inflammatory cells and without a superficial zone of necrosis. (H. & E. $\times 135$.)

and by children (Tucker and Gerrish, 1960). Few patients survive after taking sulphuric acid (Gray and Holmes, 1948). Robert's patient lived for nine weeks.

In corrosive damage to the stomach the usual lesion is pyloric stenosis of rapid onset. There is a characteristic histamine-fast achlorhydria. One is particularly likely to make a diagnosis of carcinoma from the radiographs. The possibility of carcinoma may force a laparotomy for a decision. Even at operation the condition may resemble carcinoma to a remarkable degree.

In 80% of lesions of the upper gastrointestinal tract due to acids the oesophagus is spared; 20% have concomitant gastric and oesophageal lesions. Ingestion of alkalis damages the stomach and oesophagus equally or spares the stomach (Skapinker and Crawshaw, 1954). Moynihan's (1926) series all had pyloric lesions. Strode and Dean (1950) described the microscopical lesion, which was similar to that in our case.

Treatment consists of emergency and resuscitative measures and surgery for the results of the damage. The acid should be neutralized with magnesium bicarbonate. Tracheostomy or intubation may be necessary for glottic oedema. Intravenous fluid and electrolyte and calorie intake maintenance will be required for some time.

Surgery is undertaken for the results of the corrosion. Local plastic procedures in the region of the pylorus—for example, pyloroplasty or gastroduodenostomy—are unsatisfactory because of the poor tissues and progressive fibrosis. Gastroenterostomy was the usual treatment before 1948. Gray and Holmes (1948), reviewing 139 cases, could find only three treated by partial gastrectomy. Gastroenterostomy, though often satisfactory, has a number of disadvantages—poor tissues and advancing fibrosis, stomach ulceration later, and gastric mucosal metaplasia. Strode

and Dean (1950) reported two cases treated by partial gastrectomy. Strange *et al.* (1951) and Skapinker and Crawshaw (1954) performed total gastrectomies. Hodgson (1959) advocated partial gastrectomy.

From these reported cases the best management of corrosive gastric injury appears to be partial gastrectomy. It is occasionally necessary to perform a total gastrectomy for the more unusual diffuse lesion.

We would like to thank Mr. A. B. M. Currie for allowing us to publish this case and for his help; and Dr. R. G. F. Parker for advice and his interpretation of the histological sections.

Haemolysis and Agranulocytosis Complicating Treatment with Methyldopa

Brit. med. J., 1967, **4**, 94

Methyldopa occasionally causes autoimmune haemolysis (Worledge, Carstairs, and Dacie, 1966). Agranulocytosis has also been attributed to this drug (Hallwright, 1961). A case is presented showing both these complications with demonstrable autoantibodies on the red and white cells.

CASE HISTORY

A man aged 71 suffering from hypertension had been treated with methyldopa (2 g. daily) for 16 months. For the last six of these he had also received chlorpropamide (200 mg. daily) on account of mild diabetes. When admitted to hospital his liver and spleen were found to be enlarged and both drugs were stopped, but no active treatment was given for the haematological disturbance discovered.

The results of the haemoglobin, reticulocyte, and white cell estimations are summarized in the Chart. The bone marrow showed normoblastic hyperplasia, active granulopoiesis to the metamyelocyte stage, and excessive iron storage. The half-life of ^{51}Cr -labelled red cells ($T_{1/2}^{51}\text{Cr}$) was reduced to 20 days. The serum bilirubin was 1.4 mg./100 ml. The red cell osmotic fragility was normal. The direct antiglobulin test was positive and the eluate showed anti-e and nonspecific components.

The mixed antiglobulin reaction (Chalmers, Coombs, Gurner, and Dausset, 1959) for autoantibodies on the patient's white cells was repeatedly strongly positive during the early recovery phase. Both the red and white cells remained weakly sensitized after five months.

Comment.—As the complications found in this patient bear little resemblance to the few blood disorders attributed to chlorpropamide (Grace, 1959; Karlin, 1960; White, 1962), this drug seems unlikely to have been the cause. The immune haemolysis discovered is readily attributable to methyldopa, and the agranulocytosis, associated with an autoantibody, suggests that a similar process affected the white cells.

Goodpasture's Syndrome: Survival after Acute Renal Failure

Brit. med. J., 1967, 4, 95

Goodpasture's syndrome, the combination of haemoptysis and nephritis, is being recognized with increasing frequency (Davidson *et al.*, 1966). In its classical form it comprises a distinct clinical entity to which the term "lung purpura with nephritis" has been applied (Rusby and Wilson, 1965). This paper provides the first report of a patient with this condition who recovered after an episode of acute renal failure.

CASE REPORT

A 27-year-old mechanical engineer was admitted to hospital on 9 October 1965. He gave a history of persistent haemoptysis for seven months, increasing breathlessness for three months, macroscopic haematuria for one week, and failure to pass urine for 36 hours. He was afebrile, pale, and orthopnoeic. The blood pressure was 110/70 mm. Hg and there were crepitations over the right lower chest.

Investigations.—Blood urea 170 mg./100 ml.; serum Na⁺ 129 mEq/l.; K⁺ 3.4 mEq/l.; HCO₃⁻ 17 mEq/l.; calcium 9.2 mg./100 ml.; phosphate 6.0 mg./100 ml. Liver-function tests normal. Serum proteins: total 6.1 g./100 ml. (albumin 2.6 g., globulin alpha₁ 0.4 g., alpha₂ 1.2 g., beta 0.5 g., gamma 1.4 g.). Hb 8.7 g./100 ml.; P.C.V. 30%; M.C.H.C. 29%; E.S.R. 94 mm./1st hour (Westergren); W.B.C. 13,700/cu. mm. (normal differential count); reticulocytes less than 1%; prothrombin time 17 seconds (control 11 seconds). Blood coagulation mechanism otherwise normal. Serum iron 25 µg./100 ml., total iron binding capacity 435 µg./100 ml. Coombs test, antinuclear factor, L.E. cells all negative. Antistreptolysin titre less than 100 Todd units; blood cultures negative; sputum and throat culture, a few beta-haemolytic streptococci (Lancefield group A). The E.C.G. was normal, but chest x-ray examination showed patchy consolidation at both lung bases. Numerous haemosiderophores were present in the sputum. Bronchoscopy and bronchography were normal, as were cystoscopy and retrograde pyelography.

Histological examination of renal tissue obtained on 12 October and reported by Dr. M. K. McDonald showed a moderately severe acute proliferative glomerulonephritis, with epithelial crescent formation, a few small foci of glomerular necrosis, but no generalized obliteration of glomerular structure. There was some evidence of acute tubular necrosis. Arteritis was not demonstrable.

He was treated with penicillin but continued to have haemoptyses and remained anuric. Four days after admission the blood urea had risen to 266 mg./100 ml., and peritoneal dialysis was begun with rapid improvement. On 27 October he passed urine for the first time for 20 days. On 29 October dialysis was discontinued. The blood urea which had fallen to 76 mg. rose to 138 mg., but then fell spontaneously as renal function steadily improved. During this period he had another episode of haemoptysis associated with sore throat, radiological evidence of further intrapulmonary haemorrhage, and the antistreptolysin O titre rose to greater than 2,000 Todd units. A further course of penicillin was given, and by discharge on 20 December he was clinically well and has remained well. The blood pressure was 140/90 mm. Hg, Hb 17.4 g./100 ml., E.S.R. 7 mm./1st hour, blood urea 29 mg./100 ml., and creatinine clearance 100 ml./min. There was no haematuria but moderately heavy proteinuria persisted. A second renal biopsy, performed on 29 November 1966, showed complete hyalinization of a small number of glomeruli: the remainder showed only a minor degree of endothelial swelling and focal endothelial cell proliferation and no crescents were visible.

COMMENT

Goodpasture's syndrome can be distinguished histologically from polyarteritis nodosa by the absence of significant arteritis, and is thought by some to be related to idiopathic pulmonary

haemosiderosis (Elder *et al.*, 1965). The cause is obscure, though there is evidence to suggest a hypersensitivity or immunological reaction (Duncan *et al.*, 1965). Streptococcal infection is not thought to be important, though cases with high antistreptolysin O titres have been described (Lundberg, 1963; Spreccace, 1963; McCall *et al.*, 1965).

In 1964 Benoit *et al.* reviewed 52 cases, by 1966 Davidson *et al.* increased the number to 105, and there are at least 38 further cases in the literature, bringing the total to 143. Goodpasture's syndrome is often fatal, death resulting either from massive pulmonary haemorrhage or from renal failure. Eighteen of the many patients reported as dying of uraemia have been dialysed, sometimes inadequately by present standards. Two patients who had been dialysed were still alive at the time of reporting: one has been maintained by intermittent haemodialysis (Freeman *et al.*, 1966), and the other was alive 16 months after renal transplantation (Cleveland *et al.*, 1964). Twenty-one other reported cases of Goodpasture's syndrome have survived (Bloom *et al.*, 1965; Duncan *et al.*, 1965; Elder *et al.*, 1965; McCall *et al.*, 1965; Pasternack *et al.*, 1965; Portwich and Encke, 1965; Sybers *et al.*, 1965). In the majority the renal involvement, where detailed, comprised proteinuria and haematuria without deterioration of renal function. Thirteen were treated with steroids, seven improved spontaneously, and details of therapy are not mentioned in the others.

In the present case the course of the illness was initially characteristic of Goodpasture's syndrome, but the severity of the renal failure seemed disproportionate to the pathological appearances in the glomeruli and may have been partly accounted for by the coexistent tubular changes. None the less, recovery after prolonged anuria or oliguria due to any form of glomerulonephritis is said to be very uncommon (Persoff, 1965). This is the first reported case of Goodpasture's syndrome where such recovery has occurred. With adequate dialysis other patients may survive and all uraemic patients with Goodpasture's syndrome should be treated as if suffering from potentially reversible acute renal failure.

Our patient received neither steroids nor immunosuppressive therapy, and there is no evidence to suggest that these drugs are of value during the acute uraemic phase.

Acquired Ichthyosis from Breast Cancer

Brit. med. J., 1967, 4, 96

Non-metastatic skin manifestations of malignant disease are well recognized (*Med. Clin. N. Amer.*, 1965). They include acquired ichthyosis, which is not uncommon in association with malignant lymphomas (Sneddon, 1955) but is rare in patients with cancer. Van Dijk (1963) described one case with lung cancer and from the literature collected 28 others associated with malignant disease, only one being cancer, and this was of the breast.

A case is described of disseminated breast cancer and acquired ichthyosis.

CASE REPORT

A 67-year-old woman was admitted to hospital under the care of Dr. E. W. Skipper in May 1966 with increasing pain in the shoulders, ribs, and spine of six months' duration. Her skin had been dry and itchy for three months. She denied any visual impairment.

On examination she was moderately obese with no signs of weight loss. Spinal movements were extremely painful, and the thoracic spine was kyphotic from compression fractures. The liver edge was palpable, and there was a small left pleural effusion. The

Photograph of patient's legs on admission, showing ichthyosis.

eyes were normal except for slight conjunctival injection. The skin showed generalized scaliness and dryness, and was slightly red and pigmented (see Fig.) A large carcinoma of the right breast was present with enlarged axillary lymph nodes, one of which showed metastatic breast cancer on biopsy. Malignant cells were found in the pleural effusion. Skin biopsy from the right arm was consistent with ichthyosis, and no carcinoma cells were seen. Spine

and chest x-ray films showed extensive osteolytic deposits. The fasting serum carotene and folate activity were 13 $\mu\text{g.}/100\text{ ml.}$ and 1.3 $\text{m}\mu\text{g.}/\text{ml.}$ respectively on admission and 86 $\mu\text{g.}/100\text{ ml.}$ and 3.9 $\text{m}\mu\text{g.}/\text{ml.}$ in November 1966. Faecal fat excretion over six days averaged 3.1 g./day. Other investigations, including full blood count, urinalysis, liver-function tests, blood electrolytes, cholesterol, iron, calcium, and phosphate, were essentially normal.

Stilboestrol 20 mg. daily was started on admission, and soon after she needed bendrofluazide 5 mg. daily to control leg oedema. A course of deep x-ray therapy was given to the spine, and a spinal support was supplied. One halibut oil tablet and 15 mg. of folic acid daily were given in addition for the first month. She responded well to treatment, and within six weeks her pruritus and ichthyosis disappeared and her bone pains cleared, leaving her with discomfort on spinal movements only. She remained in satisfactory health with no return of ichthyosis six months after admission.

COMMENT

There seems no doubt that the ichthyosis in this patient was related to the malignancy. On suppressive therapy her symptoms abated, general health improved, and the ichthyosis disappeared. The cause of ichthyosis in association with malignant disease is obscure. The fact that it may regress after treatment of the malignancy, as in this patient, suggests either that the neoplasm produces a metabolite causing the skin reaction or that it results from a deficiency of some substance taken up in high quantities by the neoplastic process.

Low serum vitamin-A levels as in this case have been noted in some patients. The reason is obscure and the low levels may be incidental. Our patient's dietary intake of vitamin A appeared normal, and she showed no evidence of malnutrition. Liver damage with impairment of vitamin-A storage has been suggested as a cause (Glazebrook and Tomaszewski, 1947), but it is unlikely in our patient. Vitamin-A absorption from the intestine is reduced in steatorrhoea, and Stephens and Rhodes (1964) reported the case of a patient suffering from ichthyosis, abdominal Hodgkin's disease, and steatorrhoea in whom histology of jejunal mucosa was characteristic of idiopathic steatorrhoea. Vitamin-A levels were not ascertained. No evidence of disordered bowel function was present in our patient. Ichthyosis has been reported after the use of cholesterol-lowering drugs, but our patient received no drug treatment before admission. High uptake by the cancer may have been the cause.

Ichthyosis is not described as a manifestation of vitamin-A deficiency. The skin may be dry, but hyperkeratinization in follicular and visual symptoms is usually the earliest manifestation. The absence of eye symptoms and signs and the marked skin involvement would not suggest low vitamin-A levels per se as the cause of the ichthyosis in the above case.

I wish to acknowledge with thanks the permission of Dr. E. W. Skipper to allow me to report this case, and for his help and criticisms in the preparation of this paper.

DISEASE OF THE DIGESTIVE SYSTEM

Dyspepsia

N. F. COGHILL,* M.A., M.B., F.R.C.P.

In spite of all that has been written about dyspepsia the condition remains ill-defined. Dyspepsia and indigestion are commonly and justifiably used as synonyms, and in the *Shorter Oxford English Dictionary* the meaning of dyspepsia is given as "Difficulty or derangement of digestion; indigestion." In practice most of us use these two words more to describe a group of clinical syndromes than a physical or functional state or derangement.

History-taking is helped by getting the patient to define his terms so that he and the doctor are talking about the same thing. By "stomach" most patients mean abdomen. Pain and discomfort, as felt by the patient, need to be carefully assessed. Patients sometimes use the word "vomiting" for acid regurgitation, or even merely retching. "Wind" to them may mean excessive belching or passing of flatus, or feelings of abdominal distension or discomfort.

Patients do not always recognize that they are suffering from indigestion; others use this term to describe symptoms which obviously have nothing to do with the alimentary tract. To establish the relationship, if any, of the patient's symptoms to his intake of food it may be necessary to construct a timetable of his day. The symptom-time relationships which come to light are sometimes news to the patient.

Assessment of Clinical Manifestations

Some patients with a peptic ulcer causing actual pain will give a clear succinct history leaving the diagnosis hardly in doubt. Even then there are pitfalls: the radiologist may fail to find an ulcer, or the patient may be suffering from other important physical, psychological, or social disease. Quite a number of cases need time and a sense of leisure for the history-taking that is not always immediately available in a busy out-patients.

It is good practice to try to assess whether a patient has pain or not. Though organic disease may cause no more than discomfort, it is unwise, without thorough investigation, to discount such disease when the patient experiences pain. It may be difficult to appraise the patient's chief symptom. "Terrific pain" may turn out in the end to be merely discomfort. Much will depend on the severity of the chief symptom; and on the patient's pain sensibility, his state of apprehension, and even his intelligence. Most patients understand that pain arises when something is actually hurting them, and that otherwise it is fair to speak of discomfort only. But some patients cannot categorize their abdominal sensations in this way.

A wide variety of epithets are used to describe the pain (or discomfort) of peptic ulcer, but about 7% of patients with dyspepsia are unable to describe it. In a recent survey¹ we found that only one in six patients with gastric or duodenal

ulcer complained of gnawing pain, usually thought of as common in these conditions, but that half of these patients had either gnawing or aching pain. We found that in non-ulcer dyspepsia gnawing pain was much less frequent and a feeling of distension twice as frequent as in peptic ulcer.

Some people believe that they cannot digest certain foods, often either on inadequate evidence or merely because a doctor has told them to stop eating such food. Nevertheless, fried foods upset about 50% of patients with non-ulcer dyspepsia,² but fewer (about 40%) of patients with peptic ulcer. Many patients with gall stones or chronic cholecystitis can eat butter with impunity, though cooked fats upset them.

Wind and flatulence are symptoms often complained of by dyspeptic patients. They suggest biliary disease but may occur in about half the patients with peptic ulcer and non-ulcer dyspepsia, and not infrequently accompany small intestinal disease and even heart disease; so that assessment of their clinical relevance is difficult. Nausea may occur in nearly half the patients with either peptic ulcer or non-ulcer dyspepsia, but vomiting, which used to be thought rare in uncomplicated peptic ulcer, may be seen in a quarter to one-third of such patients. Persistent vomiting may occur in patients with gall stones, duodenal obstruction, or gastric carcinoma, or as a hysterical symptom. A good appetite is commoner in duodenal ulcer than gastric ulcer, and is uncommon in gastric carcinoma.

Sometimes a dyspeptic patient loses weight. When the history is short, particularly when there is anorexia and atypical pain and the patient is a middle-aged man, the possibility of carcinoma of the stomach springs to mind. But such patients may be suffering merely from anxiety, perhaps inflamed by a family history of cancer. The loss of weight is due mainly to deficient food intake: the clue lies in obtaining from the patient other symptoms of anxiety, perhaps among them the story that although he feels hungry before a meal he feels full as soon as he starts to eat it.

Changes in Symptoms

When, after a long time, new and more severe symptoms appear it is wise to redouble the search for an organic disorder, which may prove difficult to find.

Many years ago I saw a man of 43 who for 18 years had had intermittent heartburn, flatulence, and epigastric discomfort 1-1½ hours after eating. Alkalis relieved him. For one month he had had new symptoms—nausea, and persistent lower abdominal pain unrelieved by alkalis. Full investigation, including laparotomy, failed to reveal a cause for any of his symptoms. Later he was admitted to another surgical ward as an emergency with severe pain. A registrar, nonplussed by the case, told the patient his symptoms were caused by mental illness. The patient was angry and discharged himself. Later still, at another hospital, secondary carcinoma was found in a cervical gland, and a small seminoma was

* Consultant Physician, West Middlesex Hospital, Isleworth.

discovered. The patient had lived in a house overlooking the garage where I kept my car and his widow used to come out and talk about suing the surgeon who had misdiagnosed her husband's case. Fortunately she did not do so.

It is essential for the patient to show the site of pain or discomfort when stripped. The position indicated with the clothes on is frequently misleading. If the unclothed patient with epigastric pain can "put one finger on it," indicating its localized nature, "it" is more likely than not to be due to a peptic ulcer.

Certain points in the assessment of the case will have a bearing on the treatment advised—the severity and duration of symptoms; the patient's pain sensibility (difficult to measure); the time his symptoms have kept him off work; the number of cigarettes he smokes per day; his mode of life; and his work and how he copes with it.

Diagnosis

The physical findings in most forms of dyspepsia are scanty, and for prolonged periods they may be absent. It is this, combined with the overlap of symptoms in gastric ulcer, duodenal ulcer, and non-ulcer dyspepsia, that has so far made it impossible in the majority of patients, even with computer-analysis of symptoms, to establish the diagnosis exclusively by clinical means. In about a fifth of patients with peptic ulcer the history is so atypical that it may not at first even suggest that diagnosis.³ Once it is decided that the patient has dyspepsia a barium meal examination should be performed. This will not give the diagnosis in every case, for a small number of peptic ulcers and gastric carcinomas will be missed. Gastroscopy or the use of the gastro-camera and even laparotomy may be required to make the diagnosis. In the case of patients with long histories who have been investigated in different hospitals one should avoid being unduly influenced by previous conceptions about the case, although examination of others' findings is naturally helpful. If appropriate investigation fails to reveal the diagnosis the record must be gone over again, if necessary at an extended consultation.

There is some evidence¹ that the symptom pattern in non-ulcer dyspepsia may be more helpful diagnostically than that in gastric or duodenal ulcer.

During the last 20 years hiatus hernia and its associated oesophageal reflux has become recognized as a common cause of dyspepsia. Unfortunately radiological demonstration of hernia, reflux, or both is often difficult. The condition should be suspect whenever there is complaint of heartburn and acid regurgitation in association with epigastric pain, particularly when they are influenced by posture (including lying down). Difficulties arise when peptic ulcer and hiatus hernia, both common conditions, are present in the same subject. Heartburn is probably commoner in a patient with a hiatus hernia who also has a normal mucosa or a duodenal ulcer than in one with atrophic gastritis associated with reduced gastric acidity.

Dyspepsia affects many people in whom no physical disorder can be found to explain it. Thorough search should be made for nervous causes, and this involves unhurriedly talking with the patient. The physician must appear to be interested in, and to understand, the patient's problems. Sometimes the experienced physician can sort these out, and offer adequate advice, at one consultation. Indeed, negative findings on examination and investigation may be all the patient needs for reassurance and the loss of his symptoms, particularly when there is unjustified cancerphobia. But it may be necessary to set aside adequate time by making another appointment. The medical social worker or dietitian may give valuable assistance in some of these patients, but for the most part they are the responsibility of the physician. Only occasionally will they need to be referred to a psychiatrist. Aetiological relationships

are not made less obscure by the finding, in our previously quoted survey, that worries occupying patients' minds for a large part of their waking hours beset as many patients with peptic ulcer as with non-ulcer dyspepsia. About three-quarters of all these patients related their dyspepsia to their worries.

The question of whether gastritis can cause dyspeptic symptoms is still unresolved. We have found some evidence¹ that idiopathic chronic atrophic gastritis may cause dyspepsia in some patients, but little to support the suggestion⁴ that gastritis can cause a specific dyspepsia.

Other Alimentary Causes of Dyspepsia

Disease of the biliary tract frequently causes indigestion. Gall stones or chronic cholecystitis may cause pain or discomfort in the epigastrium or right hypochondrium, and, as in gastric ulcer, duodenal ulcer, and gastritis, pain may also be felt in the back. There is usually associated flatulence and often vomiting. With gall stones the pain may be severe and prolonged and is not a true colic; "biliary colic" is a misnomer for this pain. The symptoms of carcinoma of the gall bladder, bile duct, or ampulla of Vater are usually more insidious. Jaundice is likely to appear at some stage with all disorders affecting the biliary tract; unfortunately in carcinoma it is not infrequently a late sign.

Any condition which interferes with the ability of the small or large bowel to pass food residues onward may give rise to flatulent dyspepsia and even pain after eating. Such disorders include Crohn's disease and other forms of obstruction of the small intestine, carcinoma of the colon, and ischaemic disease of the intestine. The use of new techniques for measuring intraluminal pressures in the large bowel^{5,6} has shown that some patients with unexplained abdominal pain or discomfort occurring soon after meals have irregular and increased post-prandial motility of the colon.⁷ These patients are often constipated and have what used to be termed "spastic colon," or "irritable colon." In the light of new knowledge their condition is better referred to as "functional colon disorder." Though our understanding of this condition has increased, treatment remains rather unsatisfactory.

A high serum calcium level is associated with anorexia, nausea, vomiting, abdominal discomfort, and hyperchlorhydria. Hyperparathyroidism not infrequently causes dyspepsia, and many patients with it develop duodenal ulcers.

Other, less common, causes of indigestion are intestinal worms (especially giardiasis), and hypertrophic gastritis.⁸ When dyspepsia is associated with weight loss, anaemia, hypoalbuminaemia and oedema carcinoma of the stomach or hypertrophic gastritis (Menetrier's disease) should be considered. Gastrectomy will cure the oedema in either case, for it is due to protein-losing gastropathy.

Duodenal diverticula are believed seldom to cause symptoms unless very large. Duodenitis is still a condition of unknown clinical and pathological importance. Few people now believe that dyspepsia is caused by chronic appendicitis.

Drugs

At a time when iatrogenic disease is on the increase it is well to remember that aspirin, corticosteroids, phenylbutazone, indomethacin, potassium chloride, ammonium chloride, and ferrous salts are commonly used drugs that, in the form of tablets, may cause dyspepsia (and worse) in susceptible individuals. Symptoms are less likely if these substances are taken a few minutes before a meal, which suggests that some of them cause dyspepsia by the production of a high local concentration of soluble salt or drug; if this is so it conflicts with currently held ideas about the insensibility of the gastric mucosa.

Non-alimentary Causes of Dyspepsia

Renal Disease.—Patients with renal disease are not infrequently sent first to a gastroenterologist. Renal infection or stone, or hydronephrosis, may be missed when the patient presents with dyspepsia. Pyelonephritis may of course occur in a patient with a duodenal ulcer or some other cause of dyspepsia.

Anaemia.—Patients with severe untreated Addisonian pernicious anaemia, or hypochromic anaemia, often suffer from indigestion, which always disappears, if there is no other cause for it, when their anaemia is cured.

Heart Disease.—Vague dyspepsia is associated in some patients with ischaemic heart disease (sensations of "wind round the heart," abdominal flatulence and aerophagy), or congestive heart failure (pain over the congested liver, and anorexia and possibly discomfort from a congested stomach). Diagnosis is especially difficult when, as is not rare, heart disease and hiatus hernia occur together in the same patient. The perfusion of hydrochloric acid through the oesophagus has been found^{9,10} to be a reliable test for differentiating oesophageal from cardiac ischaemic pain.

Other Conditions.—Patients with anxiety and/or depression often develop dyspepsia. It is usually not very suggestive of physical disease but often needs investigating, if only as part of the treatment of the nervous condition.

Uraemia causes anorexia and sometimes indigestion. "Fibrositis" of the abdominal wall, and a small epigastric midline hernia can also cause much confusion in the diagnosis of dyspepsia.

Accounts of dyspepsia commonly refer to a long list of other aetiological factors. In the light of present knowledge it is questionable whether, for example, allergy, unhygienic eating

habits, or an irregular mode of life (whatever that may mean) should be seriously considered as causes.¹¹

Tertiary syphilis has become rare and gastric crises now seldom trap the unwary into a diagnosis of peptic ulcer. If pulmonary tuberculosis ever did cause indigestion it was probably through associated asthenia, much as it is presumably caused in patients with untreated anaemia.

The relationship of indigestion to a variety of organic and nervous conditions has been interestingly and amusingly discussed by Alvarez.¹² Accounts of dyspepsia commonly list numerous causes of "functional" indigestion. It is tempting to speculate about the real relationship, for example, of physical fatigue, frustration, and anger with dyspepsia. Sometimes such states of mind or body must be coincidental; sometimes perhaps they and the dyspepsia have a common cause. The anxious, depressed, obsessional dyspeptic, whose overactivity is a substitute for peace of mind, is like those whose chief characteristics are their power of sustained unthinking activity, and their lack of curiosity about their destinations.¹³ Does this provide a clue about aetiology and therapy for some types of dyspepsia?

MEDICINE TODAY

Management of Rheumatoid Arthritis

"*Medicine Today*" is the television series for doctors produced by the B.B.C. Advice on the preparation of the programme is given by the Association for the Study of Medical Education.

The programme on B.B.C. 2 on 10 October was on the subject of rheumatoid arthritis. Printed below is an article prepared with the help of expert contributors to complement the television programme, which will be repeated on B.B.C. 1 on 18 October at about 11.20 p.m.

Anyone unfortunate enough to acquire rheumatoid arthritis should be given as intelligent an understanding of the disease as possible. Ten minutes of conversation can lay the foundation of many years' effective care. There are many aspects of the disease which the patient should clearly grasp from the beginning—what is going on in the joints and what are the principles of treatment, together with the facts that inflamed synovia and erosions can heal, and that in most people the disease, even if it remains active over a long period, need not progress to serious incapacity. This last piece of reassurance is particularly important after a depressing visit to a hospital outpatient department, where the most severe forms of the disease are displayed. Yet it sometimes happens that all this gets left out; the general practitioner may have obtained a consultant opinion, and each has left the job of explaining things to the other. It is quite certain that there will be a good deal of advice from elsewhere. Friends, acquaintances, books, and women's magazines, acting from one motive or another, all add their quota of misinformation, and it is

as well for the doctor to get in first. However, not all the books that have been written for patients are bad, and a few are quite useful, one of the best and simplest being *Rheumatoid Arthritis*, a handbook for patients published by the Arthritis and Rheumatism Council.*

Among the questions many patients ask are those relating to the effect of weather and diet, the value of various irregular forms of treatment (a newspaper cutting is usually produced at this stage), and the place of rest and exercise in the management of the disease. There is little doubt that symptoms in certain patients are exacerbated by weather conditions. Most dislike cold and damp, but a few find hot weather trying. Rheumatoid arthritis, however, occurs in all parts of the world, and there is no reason to suppose that climatic factors have any influence on the progress of the disease. Similarly, diet has no specific effect. Some patients with advanced disease may be unable to purchase or prepare their meals properly. A regimen of cups of tea and bread-and-butter will contribute towards iron deficiency and avitaminosis, so that where necessary arrangements must be made for proper meals, with supplementary vitamins and iron. With regard to "fringe" treatments, one can only sympathize with the desire to turn to any source of possible cure, but a firm hand sometimes has to be taken with foolish or expensive nonsense.

* Obtainable free by doctors only from the Secretary, Arthritis and Rheumatism Council, Faraday House, 8-10 Charing Cross Road, W.C.2.

Rest and Exercise

The question of rest and exercise is a difficult one on which to generalize, and both play a part in management. There is no doubt that local and general rest can lead to improvement, with diminution in joint pain and swelling and fall in sedimentation rate. This is particularly so in the early phases of the disease. A patient with moderate or severe early active rheumatoid arthritis should be given the benefit of a few weeks' rest in bed, preferably in hospital, where the break from work or household cares is complete, and where supervised physiotherapy, assessment of drug treatment, and investigative measures are more easily undertaken. Admission to hospital is not always practicable, however, nor is it necessarily desirable. Established daily routines, sometimes acquired with difficulty and practice, should not be interrupted, and older people are usually better off mobile and out of hospital. Whatever the circumstances, the posture in bed should receive careful attention. The mattress should be firm, prolonged flexion of the neck should be avoided by the use of a rigid back-rest during the day and restriction to one pillow at night, pressure on the legs and feet may be prevented by the use of a bed cage, but the use of pillows under the knees is prohibited.

Such measures help towards prevention of deformity and maintenance of function, which is the aim of treatment in rheumatoid arthritis. This is also accomplished by suitable exercises, supplemented where necessary by splinting. Exercises should be taught early and continued indefinitely. The particular movements to be emphasized depend to some extent on the individual pattern of joint involvement. Flexion contracture of the knees can be prevented by quadriceps exercises, contracture of the wrists by exercises of the forearm muscles and so on. Most of these exercises are straightforward enough, but sometimes some apparatus is desirable—for example, a rope over a pulley, easily fixed to a wall at home, can be very useful for shoulder movement. Formal exercises should be performed two or three times daily, but practised activity of many muscle groups can be carried out for a few moments at any time.

The patient should also be educated in the use of rest-splints for knees and wrists, which prevent prolonged flexion during the hours of sleeping. To summarize the rest and exercise problem: general and local rest are usually indicated during the acute onset or exacerbation of disease, and during subacute or chronic phases it is as well to avoid fatigue, taking a midday rest if possible, while active exercises must be carefully taught and continued as a habit. It is no exaggeration to say that scrupulous attention and encouragement by the practitioner in this regard can do more than anything else to maintain function in a patient with rheumatoid disease, while the plight of countless chairbound or bedbound arthritics is a testimony to the neglect of these simple measures.

Drug Treatment

Drug treatment was discussed in the television programme, and most of the principles are generally appreciated and accepted. The use of analgesics in maximum tolerated dosage is advisable in many patients, because relief of pain permits exercise and thereby assists in maintenance of function. However, pills should not be forced upon people who have a high threshold for pain and who are seen to be doing well without drug treatment. Despite all that has been written about its side-effects, aspirin is a relatively safe drug and its long-term use in rheumatoid arthritis is perfectly justified, but for patients who cannot tolerate it there are a number of alternative analgesics. Efficient analgesia and physical treatment of the sort already outlined are all that is required in the majority of patients with rheumatoid arthritis. Other anti-inflammatory agents—mainly gold salts and corticosteroid hormones—are necessary only where there is progressive and disabling disease

activity. The enthusiasm for gold salts in the thirties and for corticosteroids in the fifties has been replaced by a healthy respect for their potential dangers. The schedule of dosage for gold indicated in the programme is reasonably safe provided that a careful clinical and haematological watch is kept for incipient dermatitis, proteinuria, or blood dyscrasia. In the same way the dangers of corticosteroids are widely known, but serious trouble has usually been confined to patients on high dosage. Prednisolone 2.5–7.5 mg. daily is very unlikely to cause toxicity, and in this dosage it can often be withdrawn if the activity of the disease subsides. The drug should be considered when it confers increased mobility and functional performance and relief from severe morning stiffness, if these are unobtainable by any other means.

Long-term Management

Still, however, we are faced with the core of patients in whom the disease progresses, and where chronic disability poses various further problems in long-term management. Certain limitations of physical performance may now have to be accepted and environmental adaptation must be carefully planned. For the housewife there are numerous appliances which can be used in the house to help with cooking, housework, and personal activities. Details of these, and information about where they can be obtained, are given in another book published by the Arthritis and Rheumatism Council called *Your Home and Your Rheumatism*.† For the manual worker the necessity may arise of modification in his work, an invalid motor vehicle, or a complete change of employment, and here the help and advice of the disablement rehabilitation officer of the Ministry of Labour must be sought. And over the years there must be constant observation for various local complications which may need attention. Excessive synovial proliferation in a dorsal tendon sheath on the hand requiring excision; sudden weakness of extension of a finger due to tendon rupture requiring early suture; painful paraesthesiae in the fingers indicating a carpal tunnel syndrome, amenable to injection or to operation; progressive pain and instability in a single joint such as the wrist indicating the need for a work splint or arthrodesis; recurrent joint effusion requiring local injection of corticosteroids or synovectomy; exacerbation of joint pain raising the possibility of secondary infective arthritis; early flexion contracture of a knee requiring serial plasters in hospital; painful metatarso-phalangeal subluxation requiring suitable footwear or perhaps remedial surgery; ischaemic ulceration on the legs—these and many other problems may arise from time to time, and their early detection and successful handling play an important part in the management of the patient and the maintenance of physical, economic, and mental independence.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Albinism

Q.—A woman aged 34 is an albino with nystagmus and poor eyesight. One of her three brothers and one of her three sisters are albinos and one sister died at 10 weeks with spina bifida. Only one of her own five pregnancies has produced a live baby, and this boy died at 6 days with spina bifida. The other four pregnancies ended in miscarriages at either 9 or 26 weeks. The husband's family history is relatively unremarkable, except that one of his three sisters has congenital heart disease and a cousin on his mother's side is "mentally handicapped." What are the chances of this couple having a normal child?

A.—The recurrent abortions in this case are probably not due to genetic factors, and the risk of recurrence of miscarriage will depend on the underlying obstetric cause. If a pregnancy goes to term the risk of a neural tube malformation (anencephaly or spina bifida) is about 5%. If, however, a neural tube malformation is noted in any of the fetuses which miscarry the risk would be increased to about 1 in 10.¹

The albinism in the family is autosomal recessive and so is unlikely to appear in any offspring, provided that the marriage is not a consanguineous one. The congenital heart malformation in the husband's sister gives little or no increased risk to the children of the marriage.

Overhung Bite

Q.—What is the treatment for a child aged 9 months who has an overhung bite? The two lower central incisors overlap the upper central incisors. At what age should treatment begin?

A.—There are two possible causes for the condition. One is that a slightly aberrant path of eruption has produced a backward slope of the upper primary incisors and/or a forward slope of the lower, leading to a reversal of their normal occluding relationship. The true relation may in fact be an edge-to-edge incisor bite, but, since this would be neither stable nor comfortable, the infant reflexly adopts a slightly protrusive mandibular position as the teeth are brought fully together.

A case of this type rarely requires treatment, since it has no harmful effect. The condition may be self-eliminating by normal wear of the incisal edges during the next few years or after stimulation of such wear by dental operative grinding of the teeth. Generally, however, it disappears when the primary teeth are shed and replaced by their permanent successors at about 7 years of age.

The second and more likely cause is a fault in the antero-posterior relation of the mandible to the maxilla, which is reflected in the relationship of the dental arches. The facial

skeletal pattern—of which this is one aspect—is established early in life, normally by 3 months after birth at the latest,¹ and thereafter does not usually change to any clinically significant extent. One can therefore expect the abnormal relation of the teeth to be perpetuated in the occlusion of the permanent teeth.

Numerous radiographic analyses of the facial growth patterns of children undergoing orthodontic treatment for dental malocclusions of all types have failed to show any resultant beneficial changes in the shape or relationships of the basal jaw structures. Before this evidence became available it was common for children with structural faults of the type under discussion to be fitted with an orthopaedic type of appliance which applied backward traction to the chin by elastics from a skull cap. Despite the belief of some clinicians, careful investigation has produced no proof that this treatment either changes the shape or inhibits the growth of the mandible,² and these must therefore be considered unrealistic treatment objectives.

A later modification of the traction appliance replaced the rigid chin cup with a fabric strap across the front of the lower jaw between lip and chin, and it has been successfully used on infants to correct a reversed bite of the primary incisor teeth.³ Its effect is solely to produce retroclination of the lower primary incisors by pressure through the lower lip, but it does not alter the underlying facial skeletal pattern. While doing no harm, this treatment is in the main a waste of time, since it has little or no effect in preventing eventual malocclusion of the permanent teeth.

The differential diagnosis of the condition is best undertaken by an orthodontist (a dental surgeon specializing in malocclusion of the teeth), and could well await complete eruption of the primary dentition.

Trichomonal Vaginitis

Q.—What alternative treatment is there for persistent trichomonal vaginitis in patients in whom metronidazole causes a rash or other side-effects? Would giving antihistamines at the same time as the trichomonicide overcome the difficulty?

A.—Side-effects of metronidazole are very uncommon, though rashes are known. Such rashes are probably of the toxic kind rather than allergic, so that the administration of antihistamines would probably be ineffective.

When toxic effects are observed with metronidazole it would seem wise not to continue with the drug, for there is no threat to life from trichomonal vaginitis. Since metronidazole is the only oral form of therapy, the only alternative is some form of pessary. There are many of these dealt with in standard works of gynaecology.¹ Many

authorities would recommend acetarsol pessaries one every night for six weeks—even during menstruation, when recurrence is very common—and a further two courses of one pessary every night for ten nights at the next two menstrual periods. The efficacy of treatment should be regularly checked by pathological investigation.

Other side-effects of metronidazole therapy are leucopenia, abdominal discomfort, headache, depression, nervousness, and insomnia.²

Serotonin in Foods

Q.—In what foods is serotonin mainly contained, and which items contain the most?

A.—Information on the distribution of serotonin, or 5-hydroxytryptamine, in common foods is not readily available, presumably because it is of little interest to dietitians concerned with the nutrition of normal subjects. It is formed from tryptophan by the action of micro-organisms.

Cheeses, which owe their attractive taste to products formed by micro-organisms, contain substantial amounts of serotonin, and Camembert cheese seems particularly rich. Serotonin is also found in brain, and the enzyme necessary for its formation is present in liver, kidney, and intestines. A more exotic source of serotonin is the salivary gland of the octopus, which may possibly be eaten as a delicacy in Italy. Bananas and pineapples have also been mentioned for their high contents of serotonin and other monoamines.

In the normal subject serotonin, after ingestion in the food, is detoxicated by monoamine oxidase, an enzyme normally present in the intestinal flora. When this enzyme is inactivated by certain drugs, notably the tranquillizer tranlycypromine and drugs based on the hydrazide molecule, unchanged serotonin may be absorbed into the system, producing severe hypertensive effects. For the benefit of patients treated with these drugs more extensive knowledge of the distribution of serotonin would certainly be useful in order to tell them what foods to avoid.

Triple Vaccine

Q.—Should the pertussis component be omitted from the triple vaccine when beginning a course of immunization in a child aged 4 months who is convalescing from whooping-cough?

A.—It is irrational to administer pertussis vaccine to a child who has already had whooping-cough. He should be immunized with three doses of absorbed diphtheria/tetanus toxoid (D.T./Vac/P.T.A.H.) given at intervals of not less than four weeks and six months respectively, starting at the age of 9 months. There is no need to give the combined toxoids early in infancy. Triple vaccine (D.T.P./Vac) is given early solely on account of the hazards of whooping-cough in the very young. The antibody response, however, is improved by delaying immunization until towards the end of the first year of life.

Book Reviews

The Very Stuff of Anaesthesia

Clinical Anaesthesia Conferences. Edited by Lester C. Mark, M.D. (Pp. 326+xii. £5 5s.) London: J. & A. Churchill. 1967.

In spite of the scientific advances in anaesthesia, nothing can take the place of continuous careful observation of the patient. What is seen, however, must be interpreted so skilfully that complications can be forestalled and accidents prevented. There is a real danger just now that young anaesthetists may concentrate their attention on the more "scientific" aspects of anaesthesia to the exclusion of the more mundane but equally important ones, which draw on an accumulated store of clinical experience and knowledge. Anaesthesia still causes preventable deaths and serious complications, the majority of which are usually due to crude and preventable things, of which respiratory obstruction, drug overdose, inhalation of vomit, and circulatory failure are but a few examples.

Descriptions of these and many, many, more are to be found in the case reports gathered together in this book. These reports are based on the clinical anaesthesia con-

ferences which are published regularly in the *New York State Journal of Medicine* and which have been a feature of that journal for some ten years. The cases make fascinating reading, for not only is the discursive style used—admirably suited to the subject material—but each case report is followed by a terse and apt commentary, frequently flavoured with the unique tang of American colloquialism to drive home a point. The complications, by no means always fatal, which are described, fall under the headings of respiration, cardiovascular system, blood transfusion, regional anaesthesia, muscle relaxants, obstetrics, urethral surgery, errors in technique, and others.

This book is the very stuff of anaesthesia, and those in training will get more value out of it than many a systematic textbook. An anaesthetist is more likely to be judged incompetent in his specialist examination or in his hospital practice for failure to recognize, prevent, or treat the complications of

anaesthesia exposed here, than for his knowledge at some more abstruse level, important though that may be. The experienced anaesthetist is bound to read this book with delight, for he will find set out the excitements and triumphs as well as the disappointments which make clinical anaesthesia such a worthwhile occupation. Other physicians too will read this book with interest if not with profit. It is not only good armchair reading, but it demonstrates clearly the value, in terms of life and limb to a patient undergoing surgery, of having a competent and well-trained anaesthetist. The case reports show that anaesthesia is not simply a matter of the repetitive performance of a few technical procedures, but of the involvement of every aspect of the training that goes into a good doctor.

This is a good medical book in its own right, for it recounts clinical experience in a skilful manner. If its lessons are taken, it will benefit those who read it and their patients, and it will perhaps act as a stimulus to groups of anaesthetists in this country to do more actively what the New York anaesthetists have already been doing for so long.

W. W. MUSHIN.

Fair Play for Pharmaceuticals

Medicine at Risk. The High Price of Cheap Drugs. By F. H. Happold. (Pp. 212. 18s. Paper 12s. 6d.) London: Queen Anne Press. 1967.

History is most fascinating when presented by prejudiced rather than by impartial historians, provided one has time to consult the works of their rival protagonists. The same applies to most controversial questions; one gets a better—or certainly a more stimulating—impression by reading the views of ardent controversialists rather than by consulting the anaemic representations of impartial students.

The modern pharmaceutical industry seems to stimulate not only commissions of inquiry but also passionate controversy. For years critical onslaughts on it have been published which, though the industry in certain respects is susceptible to justifiable criticism, have often been intemperate, sensational, and hysterical. We have also had references from noble ladies in the House of Lords to "the vultures of the pharmaceutical industry making their unholy profits at the expense of the community," and even from more eminent politicians in the House of Commons that the industry has "grown fat at the expense of the public purse."

More recently the industry has found a number of apologists, of whom Mr. Happold is one. It must be confessed that their apologies are much less intemperate than the denunciations of their opponents. The author has relied on four main lines of argument, and has produced some cogent evidence to

support them: firstly, that industry has been mainly responsible for the great therapeutic progress of the last 50 years; secondly, that the drug bill forms a relatively modest and constant proportion of the cost of the National Health Service; thirdly, that financial decisions can be taken rapidly by industry without those in charge having to fear the odium of having wasted public money should the project fail; and, lastly, that the important drugs which the manufacturers produce constitute a saving to the national economy in diminishing mortality and morbidity besides contributing very significantly to the export drive.

The book is well written and traces in an interesting fashion the history of the therapeutic revolution of the last 30 years, and explains—possibly from a somewhat biased point of view—the complexities of prices, profits, and patents. This short and inexpensive volume can be confidently recommended to the many who are interested in the subject.

DERRICK DUNLOP.

Immunity Phenomena

Delayed Hypersensitivity. By J. L. Turk. (Pp. 252+ix. 80s.) Amsterdam: North-Holland. 1967.

This valuable monograph appears at a time when cell-mediated immune reactions are beginning to be understood, and it is greatly to the credit of Dr. Turk that he has succeeded in writing a book which is extremely readable and at the same time provides a serious critical analysis of present knowledge on this difficult topic.

The tuberculin or Mantoux reaction reflects complicated and long-lasting immunity phenomena, yet is independent of circulating antibodies in the accepted sense. Other examples of the dermal expression of this type of immune reaction are the virus exanthems and chemical or toxic contact sensitivity dermatitis. Of more crucial importance to human pathology is the central role played by delayed hypersensitivity phenomena in the rejection of grafted organs. A fuller understanding of this phenomenon in transplantation immunity is essential to the future development of one of the most exciting new branches of surgery, and immunological studies have already greatly contributed to the success of kidney transplantation. Delayed hypersensitivity phenomena may also be of importance in the understanding of many diseases, such as the connective tissue disorders, in which there appears to be an underlying abnormality in immunological responsiveness.

In the organ-specific type of autoimmune disorders many of the pathological changes cannot be explained by the effects of circulating antibodies alone, and the role of cell-mediated reactions is being intensively studied at the present time. Another aspect in which delayed hypersensitivity might be implicated is the defence of the organism against cancer. In all these fields research is advancing rapidly, although it is still mostly concentrated on the fundamental aspects which are being studied in experimental animals. Dr. Turk has himself contributed important original papers on the cytological events in delayed hypersensitivity skin reactions and other experimental aspects of the subject, so

that he is able to assess critically the work of others. His experience in human pathology is more limited, and discussion on what is known of delayed hypersensitivity in disease is somewhat sketchy throughout the book. This is not a serious omission considering the incomplete state of the data obtained so far in human patients.

All the experimental aspects of cellular immunity are clearly and fully reviewed and an extensive bibliography is given up to 1966, which is a credit to the speed of publication. This book will be read with interest and pleasure by all who would like to understand the basic principles underlying immunological responsiveness, and all that this implies in terms of the causation of diseases. It will be particularly useful to immunologists, immunopathologists, and workers in the transplantation and cancer immunity fields.

DEBORAH DONIACH.

Home Refresher Course in Ophthalmology

Current Concepts in Ophthalmology. By Bernard Becker, M.D., and Robert C. Drews, M.D. (Pp. 265+x; illustrated. £6 10s.) London: Henry Kimpton. 1967.

In recent years a number of publications, mainly of American origin, have appeared which provide concise and up-to-date information about some aspects of a specialty which are currently arousing interest. Such books cannot be comprehensive reference works, and, especially when of multiple authorship, they tend to devote an undue amount of space to one small subspecialty while doing less than justice to others.

Current Concepts in Ophthalmology is the combined product of 20 members of the Oscar Johnson Institute in St. Louis. Each is an authority on his subject, and most of the 21 chapters are about the length of an average paper in an ophthalmological journal. Thus they are convenient to read and digest whenever short intervals of time become available. It may be that rather too much space has been devoted to the recognized shortcomings of indentation tonometry and instruction in the use of the more accurate optical aplanation method now in very general use. Great emphasis has been placed on the value of tonography, for the gradual decrease in tension when the eye is compressed by a measured weight gives a more accurate assessment of problems of defective aqueous outflow than do simple readings of intraocular pressure. It is surprising that such a complicated method of examination calling for a close personal relationship between examiner and patient to ensure accurate results seems usually to be left to a technician, but pressure of work which renders lengthy investigations impracticable is no doubt the reason. There are good chapters on diabetic retinopathy and attempts to treat this currently little-understood disease. There is a full account of blow-out fractures of the orbit. On the other hand, there is little about retinal detachment surgery.

This book, well written and produced, is a very worthy addition to the home refresher courses which any ophthalmic surgeon can

study with advantage. It is a credit to the ophthalmic surgeons of St. Louis.

HAROLD RIDLEY.

Disorders of the Cervical Spine

Cervical Spondylosis. And Other Disorders of the Cervical Spine. Edited by Lord Brain, D.M., LL.D., D.C.L., D.Sc., F.R.C.P., F.R.C.S., F.R.C.O.G., F.R.S., F.R.R., and Marcia Wilkinson, D.M., F.R.C.P. (Pp. 232+ix; illustrated. 55s.) London: William Heinemann. 1967.

Cervical spondylosis is one of the most common diagnoses made in a neurological outpatient clinic at the present time, especially as a cause of pain in the arm, lesions of the cervical segments of the spinal cord, and recurrent episodes of vertigo. Twenty years ago this condition, even under its earlier name of cervical osteoarthritis, was only rarely recognized as the cause of these conditions. The importance of cervical spondylosis as a cause of neurological disorder is largely due to the observations of Lord Brain and his co-workers, in particular Dr. Wilkinson. Cervical spondylosis as shown radiologically is common, and the demonstration of it does not necessarily mean that the patient's symptoms are due to it. This excellent book puts the condition into perspective.

The outstanding chapter is that by Professor Ruth Bowden and her colleagues from the Royal Free Hospital on the anatomy of the cervical spine and its relation to the spinal cord, emerging nerve roots, and the vertebral artery, and it would be worth buying the book for this chapter alone. There is, however, much more of value. The accounts of pathology by Dr. Wilkinson and on radiology by Dr. A. C. Young are first class. The chapters on treatment, including a review of surgical treatment by Mr. D. W. C. Northfield and Mr. H. Osmond-Clarke, are informative, but the account of prognosis of the condition is rather disappointing in view of the authors' great experience in the disorder.

The production of the book, in particular the illustrations, is of the highest class, but there is a somewhat macabre misprint on page 117 in the description of Fig. 89.

J. W. ALDREN TURNER.

Trying to Keep Abreast

Current Therapy. 1967. Edited by Howard F. Conn, M.D. (Pp. 844+xxv. £4 11s.) Philadelphia and London: W. B. Saunders. 1967.

Three hundred and thirty-two contributors, 12 consulting editors, and an editor-in-chief have combined to produce the 19th edition of *Current Therapy*. It weighs something over 5 lb. and is clearly meant for the doctor's office rather than for his pocket. It is divided into 15 sections covering infectious diseases, internal medicine, genitourinary conditions, venereology, allergy, dermatology, neurology, rheumatic disease, obstetrics and gynaecology, and injuries due to physical and chemical agents. There are useful addenda on the contents of the

doctor's bag, electrolyte balance, and normal laboratory values. Subjects in the main sections are arranged roughly alphabetically, and each is discussed by the chosen contributor under the heading "Method of . . ." The stated object is to present the "latest approved methods of treatment for the practicing (sic) physician."

A few examples taken at random will show that the book does not always meet with the approval of at least one practising physician. Should tincture of belladonna really be recommended for the treatment of heart block? And should therapy of myxoedema begin with 2 gr. thyroid extract a day—and why not thyroxine? Three different dosage regimens are mentioned for the initial treatment of pernicious anaemia, the largest being 250 µg. cyanocobalamin on alternate days. Bethanidine is not included among the drugs used for the treatment of hypertension (it may not of course have been approved in the United States), nor is the haemolytic reaction to methyl dopa mentioned. Finally, is it necessary to place so much emphasis on quinidine dosage schedules now that cardio-version is increasingly available?

Such criticisms do not invalidate what is by any standard a most impressive performance, but they raise two questions. Is it possible to write a book on treatment which will satisfy everyone? And is it really necessary to publish such a book every year when the time interval between writing and production will put some of it out of date? Perhaps it would be better to concentrate on *standard* forms of treatment arrived at by the consensus of opinion, rather than try to present the latest, knowing that such a task is impossible.

A. PATON.

Alcoholism

Out-Patient Treatment of Alcoholism. A Study of Outcome and its Determinants. By Donald L. Gerard, M.D., and Gerhart Saenger, Ph.D. (Pp. 249+xviii. 60s.) London: Oxford University Press. 1967.

This volume reports an ambitious collaborative project for the evaluation of treatment given in a sample of outpatient clinics for alcoholics supported by State funds in the U.S.A. Eight clinics and 797 patients were included in the final analyses. Throughout the text there is an understandable emphasis on the methodological difficulties that arose in this prospective study.

Follow-up was of necessity limited to a single interview one year after the first attendance, but the authors argue the special value of progress reports on alcoholics obtained at this interval of time. The findings are extensively tabulated and there is an evident preference for simple statistical techniques. The proportion of patients abstinent for six months before follow-up interview was 13%; controlled drinking was noted in 5%, and some improvement in drinking pattern in another 12%. Against these and other ratings of improvement the authors scrupulously offset evidence of deterioration in a smaller percentage of patients. As to prognostic factors, "social stability" (a combined measure of work record and residential and marital arrangements) was by far the most significant, the

socially most disestablished having the worst outlook. There was a slight tendency for older patients to do better than younger ones, but (surprisingly) there was no difference in outcome that could be correlated with sex or education.

Most doctors treating alcoholics subscribe to the dogma that once "loss of control" (in a technical sense) has set in, moderation in drinking can never be attained thereafter, and the alcoholic must choose between total abstinence or deterioration. Drs. Gerard and Saenger join those who challenge the universal truth of this proposition.

The clinics studied and reported on in this book were among the best-financed of their type in the United States, but the authors tell us that they had grave staffing difficulties, were short of community support, and all "suffered from the burden of their task." Drug treatment was used in most cases, but disulfiram alone appeared to improve the chances of control of drinking. The eight clinics differed considerably in their staffing. Patients treated by internists or social workers did better than those treated by psychiatrists, and the clinic with a psychoanalytic orientation had the worst results of all. Patients who became abstinent showed much evidence of continuing maladjustment and unhappiness. The defaulting rate was high: 52% of patients attended on no more than four occasions, and the median duration of contact with the clinic was one month. Addictive alcoholics of previously stable personality (the group so much favoured by Alcoholics Anonymous and by psychiatrists selecting for treatment patients of good prognosis) were clearly a minority among the clientele of the eight clinics. Any service opening its outpatient doors to problem drinkers of all types might find it hard to better these American results.

The literature on alcoholism is in danger of overgrowth, but studies as painstaking as this one are still more than welcome.

DENIS PARR.

Sarah Gamp and her Forebears

English Midwives. Their History and Prospects. By James Hobson Aveling, M.D. Reprint of the 1872 edition, with an Introduction and Biographical Sketch of the Author by John L. Thornton, F.L.A. (Pp. 185+xxxi; illustrated. £7 10s.) London: Hugh K. Elliott, 1967.

James Hobson Aveling (1828-92) is known to most medical students as the inventor of a "repositor" that proved useful in cases of uterine inversion, but few are acquainted with his writings and other activities. He wrote several valuable medical historical articles, but is best known for his books on *English Midwives* (1872) and *The Chamberlens and the Midwifery Forceps* (1882). In 1873 he founded, and for three years edited, the *Obstetrical Journal of Great Britain and Ireland*, and he was one of the founders of the Chelsea Hospital for Women.

The book before us consists of "an exact reproduction of Aveling's book" on British midwives, to which Mr. Thornton has added an introduction, a short biography of Aveling with a list of his writings, and a select bibliography of more recent writings on the history of midwifery. Aveling traces the history of English midwives from the sixteenth to the nineteenth century, gives short lives of some of the better-known midwives, but confesses that on the whole "it was a sad story of indifference and neglect, of petty jealousies and sordid interests." He mentions occasions when a man-midwife (a qualified doctor) had to crawl into the lying-in room on hands and knees so that he should not be seen by the patient, to whose aid he had been summoned by the midwife. The final chapter includes a strong plea for the instruction, licensing, registration, and supervision of midwives. England lagged behind other European countries in this respect and it was not till 1902, when the Midwives Act set up the Central Midwives Board, that a new era opened in British midwifery.

This readable little volume was well worth reprinting both for the story it tells and for the light it throws on the life and work of rather a neglected figure in English obstetric history.

ZACHARY COPE.

Surgical Technique

Nouveau Traité de Technique Chirurgicale. Vol. 9. Paroi Abdominale. Sutures Digestives. Laparotomies. By Philippe Dérivé. (Pp. 473; illustrated. 115 F.) Paris: Masson, 1967.

Nouveau Traité de Technique Chirurgicale. Vol. 13. Système Porte. Rate. By Lucien Leger and Jean Patel. (Pp. 332; illustrated. No price given.) Paris: Masson, 1967.

These two volumes are part of a series of 15, each concerned with surgical technique in different regions. The authors are a number of distinguished French surgeons under the editorship of Professor Jean Patel and Professor Lucien Leger. Of the two books under review, volume 9 is concerned with herniae, techniques of intestinal anastomosis, and various indications for laparotomy, while volume 13 describes the operative treatment of portal hypertension by Leger and the surgery of the spleen by Patel.

The production is of high quality, with good print, good paper, and many excellent illustrations of the various steps in operative technique, which are described in considerable detail. There are, for example, some good drawings of the various knots tied by surgeons, and probably no method of joining two pieces of bowel together has been omitted. The illustrations of the surgery of portal hypertension and of the spleen are particularly good, and if all the volumes are of the same standard it will certainly form a valuable contribution to the literature of operative surgery, though its size may tend to make it a work of reference in a library rather than one of personal purchase.

EDWARD G. MUIR.

Books Received

Review is not precluded by notice here of books recently received.

Problems of Psychotherapy. By Herbert Zucker. (Pp. 194+viil. 48s.) London: Collier-Macmillan, 1967.

Reproduction and Man. Contemporary Science Paperback 3. By R. J. Harrison, M.A., M.D., D.Sc. (Pp. 134+vii; illustrated. 7s. 6d.) Edinburgh and London: Oliver & Boyd, 1967.

Chemical Exchanges in Man. A Physiological Essay. Contemporary Science Paperback 10. By B. F. Matthews, B.Sc., M.B., Ch.B. (Pp. 136+vii; illustrated. 7s. 6d.) Edinburgh and London: Oliver & Boyd, 1967.

Ambroise Paré. Surgeon of the Renaissance. By Wallace B. Hamby, M.D. (Pp. 251+xxi; illustrated. \$9.50.) St. Louis, Missouri: Warren H. Green, 1967.

Pharmacology. Concise Medical Textbook. 2nd edition. By J. L. Pinniger. Revised by J. R. M.D., B.Sc., M.R.C.P., M.R.C.P.E., M.D. (Pp. 279+viii. 21s.) London: Baillière Tindall & Cassell, 1967.

Diseases of the Ear. 2nd edition. By Stuart R. Mawson, M.B., F.R.C.S., D.L.O. (Pp. 554; illustrated. £5.) London: Edward Arnold, 1967.

Review of Medical Physiology. 3rd edition. By William F. Ganong, M.D. (Pp. 621; illustrated. 52s. 6d.) Oxford: Blackwell, 1967.

Handbook of Bacteriological Technique. 2nd edition. By F. J. Baker, F.I.M.L.T., F.I.S.T., F.R.M.S. (Pp. 482+ix. 75s.) London: Butterworth, 1967.

Ekg-Fibel. 7th edition. By Professor Rolf Heinecker. (Pp. 316+vii; illustrated. DM. 22.) Stuttgart: Georg Thieme, 1967.

Diccionario Medicobiologico University. Director: Dr. Alberto Folch Pi. (Pp. 1501+xxxiv. No price given.) Mexico City: Editorial Interamericana, S.A., 1966.

Intravenous Anaesthesia—S.A.A.D. 3rd edition. Based on Postgraduate Course Lectures and Material. Edited by S. L. Drummond-Jackson, T.D., L.D.S. (Pp. 230+ix; illustrated. 40s.) London: Society for the Advancement of Anaesthesia in Dentistry, 1967.

Control of Cellular Growth in Adult Organisms. A Sigrd Jusélius Foundation Symposium. Edited by Harald Teir and Tapio Rytömaa. (Pp. 434+xxiii; illustrated. £5.) London: Academic Press, 1967.

Muscle and Bone. Anatomy and Physiology. Pre-Medical Primer No. 1. By Harry Asher, M.A. (Pp. 134+viil. 7s. 6d.) London: Arlington, 1967.

Engineering in the Practice of Medicine. Edited by Bernard L. Segal, M.D., and David G. Kilpatrick, P.E. (Pp. 482+xvii; illustrated. £8.) Edinburgh and London: E. & S. Livingstone, 1967.

Intra- und Postoperative Zwischenfälle. Vol. 1. Allgemeiner Teil, Thorax. Hals. Edited by G. Brandt, H. Kunz, and R. Nissen. (Pp. 427+xiii; illustrated. DM. 98.) Stuttgart: Georg Thieme, 1967.

Secretory Mechanisms of Salivary Glands. Proceedings of an International Conference held at Birmingham, Alabama, 1966. Edited by Leon H. Schneyer and Charlotte A. Schneyer. (Pp. 389+xvii; illustrated. £5 8s.) New York and London: Academic Press, 1967.

Middle Articles

MEDICAL ETHICS

Experiments on Man

[FROM A SPECIAL CORRESPONDENT]

A round-table conference on "Biomedical Science Facing the Dilemma of Human Experimentation," organized by C.I.O.M.S. (Council for International Organization of Medical Sciences) was held in Paris on 7 October. Opening the conference, the President, Professor M. FLORKIN (Liège, Belgium), sketched briefly the historical background, pointing out that the Declaration of Helsinki was very similar to the Nuremberg Code of 1947, except that the former specified that the subject's consent should be obtained in writing. Even having obtained this, however, the research worker should always consider the underlying motivation, and he cited one investigation at Harvard Medical School which had shown that 60% of volunteers were maladjusted, and were thus completely unrepresentative of the general population.

Discussing experimental procedures on the central nervous system, Sir JOHN ECCLES, F.R.S. (Chicago, U.S.A.), instanced several which in his view were clearly allowable; moreover, the subjects were often the investigators themselves. These included "psychophysics," such as the stimulation of vision, hearing, and balance. No after-results were seen from these procedures, which essentially had to be done in man, since the object of the work was to investigate conscious experience. Similarly, investigations on reflexes and most conditioning and learning experiments in man were acceptable. When full safeguards were taken another category of procedure was also allowable—namely, the stimulation of the exposed brain during neurosurgery. In some cases stimulation might be necessary to determine the site of a lesion and to treat it effectively. In others, however—as in the treatment of Parkinsonism—the procedure might be quite unrelated to treatment. This aspect must be explained fully to the patient, who also must be told of his right to refuse permission. Nevertheless, Sir John continued, a high proportion of patients volunteered to undergo this procedure, which was free from the risk of damage to the brain and had led to some fundamental discoveries about the threshold of consciousness.

He was extremely concerned about certain experiments which had used indwelling electrodes inserted through trephine holes in the skull. These might have multiple leads and be maintained in position for months, and undoubtedly they caused "fantastic" damage to the brain. Since the subjects were often psychotic they could never be expected to understand the procedure fully, and the damage to the brain could not be justified under any circumstances. Concluding, Sir John called for the development of large

colonies of anthropoid apes, in which most of this type of work could be done.

Drug Testing

Professor B. N. HALPERN (Collège de France) said that testing drugs in animals did not necessarily exclude all their risks in man. In particular the metabolism of a drug might be completely different in man from that in most experimental animals. For this reason he felt that preliminary tests with small doses of a new drug should be carried out in man. Once the metabolic pathway had been determined, the drug should be tested extensively in those animals which were known to have similar biochemical processes to man. He emphasized that rigid legislation for human experimentation in therapeutics was impossible, since the risk to be run was proportional to the seriousness of the disease. There was a great need to develop the discipline of clinical pharmacology, which would provide the necessary bridge between the laboratory worker on the one hand and the clinician on the other.

Professor A. GELLHORN (Columbia University, U.S.A.) said that probably the 60–70% of patients with incurable malignant disease constituted the largest identifiable group of persons regularly submitted to therapeutic tests. Patients' families demanded some sort of treatment; the doctor felt he must do something; the patients often volunteered for any form of treatment; while the results of cancer research in animals could be applied to man only rarely. There were two main types of research carried out on patients with cancer: firstly, work which might possibly benefit the individual (such as the use of new drugs and surgical procedures, and non-conventional radiotherapy); and, secondly, work having no relevance to the patient's disease. In his view the latter was never justified. He believed that no form of experiment was justifiable on the basis that the patient was going to die anyway—such experiments on the "hopeless case" might eventually diminish the doctor's concern for human life. If the patient was moribund no useful conclusions could be derived from any results, while, if he was not, how could the doctor be certain of the hopelessness of the position?

Code of Conduct

Continuing, Professor Gellhorn asked two questions. Could there be laws on human experimentation? He thought not. Should decisions about experiments be left to the

individual? Again, he thought not, because it placed too much power in one person's hands. He proposed a procedure for the decisions based on six main points. Firstly, work should be carried out only with the hope of improving the patient's condition. Secondly, there should be a reasonable prospect of success based on animal and other work. Thirdly, a protocol for control work and safeguards should be drawn up. Fourthly, the proposed research programme should be reviewed by the worker's peers who were knowledgeable in the particular field. Fifthly, the results should be systematically collected and analysed by independent observers. Lastly, the patient's written consent should be obtained before any procedure was undertaken. Though he believed truly informed opinion was impossible, this consent would give the patient his rightful status as a person and not as a mere experimental animal.

Kidney Transplantation

Professor J. HAMBURGER (Paris, France) discussed the mortality risks run by the live donor of a kidney, pointing out that a study in Boston had shown these totalled 0.12%—an immediate operative risk of 0.05%, together with a remote risk of 0.07% for subsequent disease which might develop in the remaining kidney. Now that improved techniques had raised the one-year success rate of live-donor kidney transplantation to about 75%, he asked whether it was justifiable to accept the offer of a kidney from a donor. Since this might save a patient's life, people were beginning to revise their critical objections, drawing up a balance sheet between the risks and the prospects of success. Professor Hamburger emphasized that the donor must be an active volunteer—completely warned of all the risks; well-motivated (for example, to save a relative's life); subjected to no moral or financial pressure; and mentally healthy (usually determined by psychological testing). Concluding, he pointed out that in June 1967 Italy had promulgated a law defining the conditions for accepting a live graft which would protect both the donor and the doctor. In his opinion all countries with units undertaking transplantation procedures should follow this example.

Unwise Control

Professor M. B. VISSCHER (University of Minnesota, U.S.A.) considered that progress in knowledge would be seriously restricted if

Professor Gellhorn's criterion of individual benefit was followed, though he emphasized that he was not advocating harmful procedures. At present there were two possible legal checks on wrongful experimentation—firstly, by prosecution for acts already undertaken, and, secondly, by some form of licensing of the experiments. Whereas the latter method was well suited to food-processing, for example, he questioned whether it could be applied to clinical experiments. Professor Visscher cited the British licensing system for experiments on animals, saying that this had saved workers from the harassments of the antivivisectionists; on the other hand, it had virtually barred students from performing a number of types of valuable experiments, as well as hampered surgeons in training. Moreover, British law did much to protect animals, but little to protect man.

Continuing, he said he would deliberately instance some extreme examples of restrictions on research procedures in his own university. There research studies on body fluids—blood, faeces, and urine—could not now be carried out without the informed consent of the patient and approval of the project by a committee of the worker's peers, whether or

not the specimens were to be obtained specifically for the research work or were merely left over from routine testing. Moreover, Professor Visscher thought that more patients were now dying from the want of life-saving drugs which overzealous and cautious departments had delayed in licensing than would have ever been at risk from the drugs themselves. The core of the ethical problem was the propriety of research with real hazards to the patients, and he believed that the solution was to put more of the onus of responsibility on panels of non-Governmental research experts.

Achieving a Balance

Dr. A. E. CONFREY (National Institutes of Health, Bethesda, U.S.A.) said that the underlying principle of the United States Public Health Service was to achieve a balance of Federal and local responsibility for the control of research. The task of the central authority was to lay down general standards, and to require adherence to them, without seeking to define the detailed pro-

cedure for an individual research project. At local level the research project should be reviewed and continually scrutinized by a university or hospital research committee which had no vested interest. Nevertheless, ultimately the research scientist was responsible for the quality of research investigation.

Professor A. DE MURALT (Berne, Switzerland) questioned how many students were getting any training in medical investigations. There was a danger that the availability of money for clinical investigation, the increase of sophisticated machines, and the growing number of new drugs might tempt workers into unethical procedures. Moreover, the large-scale financial support of university laboratories by pharmaceutical companies might tend to diminish the former's independence. Supporting the proposal for the introduction of clinical pharmacology departments on a large scale, he thought that research should be done by large groups on worthwhile problems which had been carefully screened. Though Government regulations might discourage research, permission or a licence by an uncommitted body of the worker's peers would be a justifiable and suitable safeguard.

CONFERENCES AND MEETINGS

British Association of Physical Medicine

[FROM A SPECIAL CORRESPONDENT]

This year's Annual Provincial Meeting of the British Association of Physical Medicine was held at the Nuffield Orthopaedic Centre, Oxford, on 30 September, under its President, Dr. F. S. COOKSEY, with Dr. PHILIP NICHOLS (Oxford) as the host. The theme of the morning session was the rehabilitation of the severely disabled, and included exhibits and demonstrations of many mechanical appliances and aids of all kinds, together with current research projects relating to powered prosthetics being developed in collaboration with the department of engineering science in the University of Oxford.

Suppression of Menstruation

Emphasis was also placed on the importance of clinical assessment of such patients. To illustrate this Dr. ANNE HAMILTON (Oxford) discussed the suppression of menstruation as a technique of particular importance for severely disabled women. She pointed out that the problem of the physical management of perineal toilet during menstruation is one of considerable distress to many severely disabled women. A method of complete suppression of the menstrual cycle by inducing pseudo-pregnancy with ethynodiol diacetate 2 mg. and mestranol 0.1 mg. (Metruken) was described. Experience over the past year had shown that this could be extremely successful. Not only were the patients more comfortable, but in several there was an improvement in their mental

state, a feeling of well-being, a steady rise in the haemoglobin level, and healing of bedsores. Four patients stopped taking the drug, but this was the result of factors outside the immediate clinical management. Dr. PHILIP NICHOLS suggested that in those patients where this method was successful on a short-term basis hysterectomy should seriously be considered, because pregnancy was usually particularly inadvisable.

Degenerative Changes in Hip Joints

Dr. P. G. BULLOUGH (Nuffield Foundation) described the degenerative changes observed in the hip joints in 50 patients examined at necropsy. The first signs of arthritis had been observed in patients as young as 15 years, and they were almost invariably present in every patient over the age of 25. These changes appeared to be confined almost exclusively to two main areas—firstly, on the roof of the acetabulum, and, secondly, on a strip below the head of the femur. Degenerative changes in these sites, however advanced, were not necessarily associated with symptoms, as these were non-weight-bearing areas. Why they occurred and their significance were not clear, but Dr. Bullough noted that once these changes extended on to the weight-bearing surfaces around the rim of the acetabulum and corresponding areas on the head of the femur the clinical picture of osteoarthritis began.

Mr. B. T. O'CONNOR (Oxford) reported a series of experiments designed to maintain a continuous negative charge across an osteotomy site in the metatarsal of a rabbit in the hope that healing would be accelerated. In several of the subjects there was evidence that this occurred, but as yet the techniques of the procedure were not entirely satisfactory.

Management of Haemophilic Arthropathy

Mr. A. W. STEEL (Oxford) said that working in close proximity to a large haemophilia centre had enabled surgeons to gain considerable experience of the management of haemarthrosis in the bleeding disorders. The primary aim of the surgeon was to prevent the severe joint deformities which follow repeated bleeding. Ideally bleeding into joints was treated by plasma transfusion within two to three hours of onset. A total of 414 episodes had been treated in this way as day cases in the last year. About 100 established haemarthroses required admission and were treated by plasma, immobilization, and rapid restoration of function at the earliest opportunity. Aspiration of joints was carried out in many cases under plasma cover. Established contractures and deformities were dealt with by plaster techniques and corrective surgery under cover of anti-haemophilic globulin.

Correspondence

Letters to the Editor should not exceed 500 words.

Laboratory Screening Procedures

SIR,—Your report of the symposium on laboratory screening procedures (30 September, p. 859) raises a number of important points. The problems of population screening are immense, from both the technical and economic viewpoints. Both Professor W. M. Davidson and Professor J. G. Scadding rightly stress that the radiological screening of the population produces benefits to the community beyond that to individuals in that the spread of tuberculosis could be defined and checked. May I suggest that the economic consequences of certain diseases spread beyond the affected individual, and therefore need to be considered as a "fall-out" effect, which is as important today as such factors as the spread of infectious disease. The effect of undetected illness on family income and nutrition at one extreme of the social scale and on the judgement of persons in responsible positions at the other are problems that we have all met at some time or another. The aims and desirability of population screening programmes will be better defined when investigations such as that initiated by Professor L. G. Whitby have been going for some time and their implications for the community digested.

In hospitals we have had screening programmes since the systemization of clinical medicine seriously began in the nineteenth century. Each patient admitted is submitted to a general examination, and no doubt has his height and weight measured, his temperature taken at intervals of time, and his urine tested for protein, glucose, etc. The extension of this principle to laboratory tests such as Dr. T. P. Whitehead and his colleagues have carried out so ably in Birmingham should not excite too much surprise. The advances in both analytical and data-processing technology are placing powerful tools

in our hands which are changing our traditional ways of investigating patients. In a semi-automated laboratory it is often simpler to perform a standard group of tests simultaneously than to perform any combination of these tests randomly selected by the clinician. It is the introduction of such machinery which has made the prospect of biochemical screening a practical one.

The selection of analytical methods by the manufacturers of large analytical machines has often been determined by the question: "How many of the most common biochemical or haematological tests can we perform at once on one sample?" As clinicians and pathologists I would suggest that we ask ourselves instead, "Which disease processes do we most commonly fail to identify early in hospital, and how can we best detect them?" Modest screening schemes such as the measurement of haemoglobin, plasma glucose, and urea would not be expensive to mount, and few patients with diabetes, anaemia, or renal failure who had been admitted to hospital for other reasons would remain undetected. (It may well be more effective and cheaper to detect diabetes among hospital admissions in this way than by using the time of a trained nurse in testing urines, possibly missing 10–20% of the mild cases.)

For the future we should remember that the number of tests which can be performed routinely on one sample (profile processing) is going to depend on the economics of laboratory organization. This is dependent on the relation of capital employed on buildings and apparatus to revenue expenditure on technical skill and materials.—I am, etc.,

M. G. RINSLER.

Group Pathological Laboratories,

Aspirin and Gastric Bleeding

SIR,—Once more aspirin is under attack, and paracetamol is recommended as a better analgesic for occasional use in your leading article "Aspirin and Gastric Bleeding" (30 September, p. 810). The reason given for this is that aspirin may cause gastric bleeding, whereas paracetamol does not. But then no drug is totally without side-effects, and considering the quantities in which aspirin is taken (quantities which seem to take your leader writer by surprise) it must still be considered one of the safest drugs we have. If paracetamol were taken in equal quantities would we not start worrying about the blood dyscrasias it produced, or some other side-effect?

Moreover, paracetamol is not as good a drug as aspirin in several respects, as I

pointed out in your correspondence columns only last year (9 April 1966, p. 918). It is a weaker analgesic, and has not the satisfying sedative effect in children (even some adults find aspirin useful as a mild sleeping tablet). So far as cost is concerned, aspirin wins easily at 1s. 3d. for 100 tablets (300 mg.) against paracetamol at 3s. 8d. for 100 (250 mg.), these being the local over-the-counter prices. Even soluble aspirin (if it is considered better than the ordinary form) is only 2s. 3d. for 100 tablets.

But the side-effects of taking aspirin certainly can and should be reduced. Firstly, products containing it should never be advertised as being good for indigestion or stomach ache. (The last two cases of severe haematemesis I saw were both in people who had been taking

aspirin for recurrent indigestion.) Doctors have a responsibility for telling people with proved or suspected peptic ulcers to avoid the drug, and substitute paracetamol—a responsibility they often forget. They should also point out, of course, that even taking paracetamol is not the way to deal with their stomach ache, and give advice how best to do it. Finally, the public must slowly be educated to accept many of the minor, short-lived aches and pains of life, and not to depend on drugs (even relatively safe ones like aspirin) to overcome them.—I am, etc.,

T. C. DANN.

University College of Swansea,
Glam.

SIR,—Your leader-writer on the above subject (30 September, p. 810) wonders why the gastric mucosa has at times increased susceptibility to aspirin. In a fairly recent article,¹ based on a four-years observation, I suggested that the factor or factors for this increased susceptibility might be found by regarding the whole man and not by too narrow a consideration of the stomach in isolation. I had a strong impression that such factors as prolonged worry, emotional stress, infections, and chronic painful disorders—for example, arthritis of the spine—might well be factors of this type.

If I may again quote three writers² who came to a similar conclusion: "The gun must be loaded in order for an explosion to occur when salicylates pull the trigger." To me mental stress, prolonged fatigue, physical pain, and infection seemed to be effective "loaders," and with these sometimes went irregular meals, alcohol, and heavy smoking. Reference to the other many authors whose evidence has pointed the same way will be found in my paper.—I am, etc.,

G. H. JENNINGS.

REFERENCES

- Jennings, G. H., *Gut*, 1965, 6, 1.
- Grossman, M. I., Matsumoto, K. K., and Lichter, R. J., *Gastroenterology*, 1961, 40, 387.

SIR,—The concluding sentence of a leading article (30 September, p. 810), "Surely the time has come to advise patients to keep this drug (paracetamol) rather than aspirin in the medicine cupboard," has been written without consideration of the wider implications of such advice. We do not doubt that the change would be advisable from the point of view of reducing the incidence of gastric bleeding.

Aspirin, however, is one of the drugs most commonly involved in self-poisoning in adults and accidental poisoning in children. Although the annual consumption of salicylate preparations in Great Britain is estimated at 4,000,000,000 tablets, in 1965 about 12,000 patients were admitted to hospital in England and Wales for treatment of salicylate poisoning, and only 264 died. This comparatively low mortality is largely due to awareness of the problem and a rapid

response to specific therapy, even when large numbers of tablets are consumed.

On the other hand, experience of paracetamol poisoning is very limited, but acute liver necrosis and death feature prominently in recorded cases.¹⁻³

Indeed, the manufacturers of one brand of paracetamol, very responsibly, give in their brochure information relating to a 13-year-old girl who died after taking 30 tablets. Post-mortem examination revealed massive diffuse toxic necrosis of the liver. The onset of liver disease in paracetamol poisoning may be delayed several days, and it is possible that survival from serious intoxication may be complicated by residual liver damage. The toxic effect of 50 aspirin tablets, a common overdose, is very much less than those that might arise from ingestion of a similar number of paracetamol tablets. Moreover, there is no adequate therapy for this type of poisoning.

Should the advice of your leader be accepted and paracetamol become as readily available as aspirin is at present, a greatly increased incidence of paracetamol overdose is inevitable. We consider that the resulting mortality and morbidity would be greater than that from aspirin poisoning, and certainly would not warrant acceptance of the change you have so strongly advocated.—We are, etc.,

Treatment of Poisoning by Antidepressant Drugs

SIR,—In view of the increasing incidence I was pleased to see the article by Dr. C. M. Steel and others (9 September, p. 663) on the problem of the poisoning of children by antidepressant drugs.

There are two characteristics of this type of poisoning which I feel are not sufficiently well recognized, but which are of the utmost importance in the management and which deserve further emphasis. Firstly, that in children an extremely low dose (far less than the L.D.₅₀ in experimental animals) can be fatal; and, secondly, that recovery from the initial coma can be followed, after an interval, by a sudden and unheralded death. The necessity of appreciating these points fully is obvious.

My own experience is confined to opipramol, which is another, tricyclic compound closely re-

lated to imipramine and amitriptyline, and I have described a fatal case of overdose with this drug in a 14-months-old child (awaiting publication). The salient features of this case demonstrated the characteristics above. The dose taken was small—1,000 mg. in a 9-kg. child—that is, 110 mg./kg., which is less than one-third of the L.D.₅₀ for dogs (400 mg./kg.). There was an apparent recovery from the initial coma, and this was followed by a sudden and completely unexpected death about 18 hours after ingestion. The child was treated without the knowledge of the special features of antidepressant poisoning by curarization, intermittent positive pressure respiration, and forced diuresis. Consideration of the problem after this unsatisfactory outcome led us to much the same conclusion as Dr. Steel and colleagues for future management.

Of the 18 cases of opipramol overdose which have been reported six have been fatal, and four of these have been attributed to sudden cardiac arrest. At least three of the fatal cases had taken only very modest doses—much less than the L.D.₅₀ in dogs.¹ Only two of these cases, however, have been documented.^{2,3} In the case of opipramol poisoning the following additional information might also be useful. Less than 1% of the total dose is excreted unchanged in the urine; and serum levels remain extremely low even after intravenous administration (a dose of 10 mg./kg. produces peak levels of only 0.25–0.3 mg./100 ml.).⁴ This endorses the view that forced diuresis or other active measures are contraindicated. Also it has been shown that opipramol suppresses A.C.T.H. formation in experimental animals,⁵ and this suggests that in the event of collapse steroid cover might be appropriate.

It is hoped that these further observations might be helpful in deciding on the management of what must be among the most tragic of cases if fatal.—I am, etc.,

Psychotropic Drugs

SIR,—It is important that the Dunlop Committee and your other readers should not be given the impression that all psychiatrists are as enthusiastic as is Dr. William W. Sargent over the antidepressant drugs (30 September, p. 861). While one must acknowledge that Dr. Sargent has probably an unequalled experience of speaking and writing about the monoamine oxidase inhibitors, there are many clinicians "working whole-time at the bedside" who have used these drugs in thousands of cases during the past decade, and who have become increasingly doubtful of their value. On the other hand, there is no doubt whatever that they cause dangerous side-effects and no doubt whatever that they have killed patients. Dr. Sargent's letter adds another death to the growing list—that of a patient said to have tempted providence by eating cheese. She could equally well be said to have tempted providence by eating iproniazid.

The Medical Research Council is presumably well able itself to take care of the charge

that it has "already made rather a fool of itself" by carrying out a controlled trial of phenelzine on depressed inpatients which showed the drug to be somewhat less effective than a placebo. Those who know the details of this trial will know also that Dr. Sargent's description of it was not accurate. The M.R.C. trial performed a useful service in indicating that phenelzine was of no value in the treatment of cases of moderate or severe depression as defined in the terms of that trial; previously it had been widely prescribed for such patients. Of course, one must not generalize from this to say that it is of no value in any condition whatever.

But why is it so wrong to recommend that certain drugs should not be used for psychosomatic conditions unless proved to be valuable in controlled clinical trials? There is no good reason why psychiatry should continue to run on a lower level of scientific objectivity than other medical specialties. If physicians at St. Thomas's Hospital have found phenelzine and isocarboxazid to be so effective in so many psychosomatic states they should have little difficulty in carrying out a properly controlled trial to demonstrate this. The ethics of this suggestion are, as always, capable of being confused by someone who will say that we already know one particular treatment which is strikingly and uniquely effective. But such a trial, they could reassure themselves, may perhaps influence those of us who have used the same treatments in those same conditions and found them to be not only risky but also strikingly ineffective.—We are, etc.,

Advantages of Health Centres

SIR,—Drs. E. Lace and H. I. Howard in their letter (7 October, p. 49) about their experience at the William Budd Health Centre are right to stress the many gains which accrue to the doctors and their patients working in such health centres. However, in their swipe at the so-called armchair critics and advisers have they not committed the same offence of which they accuse?

Their personal experience of privately owned centres must be limited. Thus their conclusions in that direction must not be allowed to discourage until proved correct. The many centres which are being developed up and down the country are not exactly the financial hare-brained undertakings which Drs. Lace and Howard infer. Further, I would like to remind your readers that almost all the pioneer attachments and use of ancillary help, whether seconded from local authority or as private ventures devolving around such privately owned centres, were published from such partnership or group practice centres or single-handed practices. The examples of general practice/local authority co-operation come from far and wide, and not necessarily from a health centre in the true sense. This of course is not synonymous with health centre development not being desirable. On the contrary. But the profession must not be left in any doubt that it can itself proceed to develop facilities

and centres, not to mention the help the finance corporation can give in this.

Quite correctly Drs. Lace and Howard advocate conferences on these subjects. One was held in 1965, and one earlier this year. Further such meetings are planned.—I am, etc.,

Edinburgh.

E. V. KUENSSBERG.

Intestinal Obstruction

SIR,—Your leading article "Intestinal Obstruction by Food" (24 June, p. 782), which comments on my paper "Intestinal Colic Caused by Food,"¹ is quite amusing and well taken. I would like to draw your attention, however, to a misinterpretation of my paper which, I believe, has some importance. Your article states that the condition is "a rare event in any surgeon's working life." While it is true to say that complete organic obstruction caused by food is in fact a rare event, I tried to give some evidence in the paper to show that incomplete and temporary episodes of food obstruction are probably not uncommon. Such episodes may be responsible for many otherwise undiagnosed bouts of intestinal colic which patients suffer not infrequently without ever attending a doctor's surgery.—I am, etc.,

Subcutaneous Atrophy After Local Corticosteroid Injection

SIR,—In the article by Dr. Ann Beardwell entitled "Subcutaneous Atrophy after Local Corticosteroid Injection" (2 September, p. 600) the author states that she could find no reports in the literature of this complication occurring in patients treated for arthritis. I would like to call her attention to an article by James T. Cassidy and Giles G. Bole.¹

In the same issue of the *B.M.J.*, under "Correspondence" (p. 614), Dr. Raymond Greene advocates the use of propranolol in myxoedema on the basis that thyroxine enhances beta-adrenergic activity. I would like to point out that the concept that thyroid hormone augments the actions of catecholamines on the cardiovascular system has been refuted both in man^{2,3} and in animals.^{4,5}—I am, etc.,

SIR,—I read Dr. Ann Beardwell's paper (2 September, p. 600) with great interest, as I have noted this complication after steroid injections for "tennis-elbow," par-

ticularly when several injections have been given at the same site. The effect can occur with hydrocortisone acetate 25 mg. per ml. In my experience it has been more obvious in those with little subcutaneous fat to begin with, and subsequently, on clinical examination, there appears to be a total absence of subcutaneous tissue between the skin and the periosteum. The skin itself appears more transparent and very reminiscent of the "transparent skin" described in rheumatoid arthritis.

Two cases similar to Dr. Beardwell's were recorded by Iuel and Kryger.¹ They noted that in one case there was brown discoloration of the skin over the atrophic area, while in the other the atrophic skin failed to tan after exposure to sun. I have noted a similar disturbance of pigmentation.—I am, etc.,

Cyst of Popliteal Artery

SIR,—We read with interest the article on cystic adventitial disease of the popliteal artery by Mr. G. J. T. Lewis and others (12 August, p. 411). We have recently encountered such a case in which we made some special studies.

Three months before admission the patient, a lighterman aged 32, experienced a severe pain in the right calf while climbing a ladder. Since

the swelling revealed a translucent wall with colourless contents shining through. Without applying clamps the cyst was opened and the jelly-like material sucked out. It was then seen that there was a small opening in the floor oozing the same material and leading to a second cavity projecting into the lumen and apparently the cause of the x-ray appearance. A probe inserted into this hole passed 1.5 cm. distally (Fig. 6). The outer cyst and roof of the deeper cyst were

FIG. 5

then he had claudication at 25–30 yards (22–27 m.), and occasional rest pain in the right foot. On examination he was a well-built healthy man. At rest all peripheral pulses were present and equal. Following exercise, however, the right leg below the knee became white and cold and the dorsalis pedis and posterior tibial pulses disappeared, returning slowly after five minutes' rest.

The cutaneous pulses from the pulp of the toes measured with a photo-electric pulse meter (kindly loaned by Dr. R. H. Fox) showed corresponding changes (Figs. 1 and 2). An aortogram (Dr. L. Morris) showed an entirely normal arterial tree apart from a crescentic filling defect almost totally occluding the right popliteal artery (Fig. 5A), and a diagnosis of cystic degeneration was made.

At operation the popliteal artery presented a hemispherical swelling 3 cm. by 1.7 cm. situated on the p-stero-medial aspect. Apart from unusually dense adhesions the artery appeared otherwise normal. Full exposure of

excised and there immediately presented the normal shape of the artery, cylindrical, smooth, and of a light plum colour. The floor was presumed to be the intact medial coat. The adjacent tissue was then stitched over. Following this there was excellent pulsation in the artery.

Histologically the cyst wall was composed of fibrous tissue with occasional elastic fibres.

FIG. 6

The pulse meter recordings after operation show a return to normal of the amplitude and form of the pulse wave both before and after exercise (Figs. 3 and 4). Postoperative arteriography shows how completely the arterial lumen returned to normal.

The sudden onset of symptoms in our case may have been due to the floor of the superficial cyst giving way, resulting in the extrusion of the contents into the dissection plane of the vessel, so forming an internal projection which constricted the lumen. To postulate synovial cell rests in the arterial wall seems embryologically unlikely. The cystic fluid is identical in colour and consistency to that of a ganglion. We have always supposed a ganglion to be a degenerative cyst containing collagenous material and caused by trauma. We feel a *prima facie* case exists for postulating such an aetiology for the arterial cysts, although the mode and nature of the trauma is more difficult to visualize.

Dr. G. Leaf's comprehensive analysis of the cyst material has shown that it is not pure collagen. A similar analysis of ganglion contents might be illuminating, and significant differences would need to be shown before the similarity between the two types of cyst can be rejected.—We are, etc.,

HERMON TAYLOR.

R. S. TAYLOR.

Elusive Popliteal Pulse

SIR,—Your comments on palpation of the popliteal pulse (5 August, p. 326) are well taken. However, I take exception to your statement that "a pulse that cannot be felt . . . is surely absent." Work with transcutaneous Doppler ultrasound was shown to be much more reliable than palpation, particularly in this elusive area. As reported in the literature,^{1,2} absence of the pulse does not necessarily mean absence of flow, even indeed of adequate flow. Obviously this is of particular importance in the evaluation of distal run-off following graft or bypass arterial surgery.—I am, etc.,

Retinal Changes after Cardiac Arrest

SIR,—Sir Stewart Duke-Elder has kindly pointed out to me that my suggestion that observation of retinal changes after cardiac arrest is of grave prognostic significance (16 September, p. 722) is, alas, not as original as first thought. A fuller description of the changes that may be seen is given in his reference work.¹

It is of interest that the suggestion about the significance of retinal changes when considering resuscitation was originally made by Salsbury and Melvin more than 30 years ago as a result of experimental work.² Twenty years later Kevorkian³ confirmed this after observations made in two human subjects who

suffered cardiac arrest while at normal body temperatures (the retinal changes are different in hypothermic circulatory arrest). However, as Sir Stewart points out, quantitative confirmation about the usefulness of this physical sign in humans has been lacking, and I am grateful for having had the opportunity of providing these data.

In this connexion the number of cardiac arrests personally attended is now 95, of which 43 had the circulation initially restored. Retinal changes have now been observed on 20 occasions, and on these occasions there was failure in restoring the circulation with the exception of the decerebrate child described in my memorandum. This contrast speaks for itself.

It would thus appear that the suggestion that observation of retinal changes after cardiac arrest is of grave prognostic significance, proposed as a result of experimental studies by Salsbury and Melvin and confirmed qualitatively in man by Kevorkian, has now been confirmed quantitatively. Observation of these changes would provide an objective yardstick for deciding whether to attempt to resuscitate or not.—I am, etc.,

Queen Elizabeth Hospital,

Pernicious Anaemia and Intestinal Malabsorption

SIR,—We were interested to read Dr. C. G. Riley's report of a case of pernicious anaemia and intestinal malabsorption (9 September, p. 657).

There are several reports¹ in the literature of cases of jejunal diverticulosis associated with achlorhydria demonstrated by the augmented histamine test, and in none of them is there conclusive proof of the coexistence of Addisonian pernicious anaemia (P.A.). To establish this diagnosis in the presence of coexistent jejunal diverticulosis it would be necessary to demonstrate severe reduction of intrinsic factor (I.F.) production to the levels found in pernicious anaemia. The demonstration of intrinsic factor antibody in the serum is in itself insufficient proof.² Indirect evidence of inadequate intrinsic factor production may be obtained by the use of the Schilling test and its modifications. In uncomplicated P.A. the urinary excretion of ⁵⁷Co vitamin B₁₂ should be restored to normal levels by the addition of oral I.F.³ In jejunal diverticulosis a preceding course of antibiotics is usually sufficient to restore the urinary excretion values to normal without oral I.F. being given. In a few cases a combination of oral I.F. and antibiotics was necessary to restore urinary excretion to normal,⁴ suggesting inadequate endogenous I.F. production (i.e., coexistent P.A.). However, as there is evidence⁵ to suggest that even in the presence of adequate endogenous I.F. production additional oral I.F. may enhance vitamin-B₁₂ absorption in cases of jejunal diverticulosis, this conclusion may not be valid. Unfortunately Dr. Riley's case report fails to document severe depression of endogenous I.F. production. The complexities of interpreting in-

direct evidence in the situation of multiple pathology are such that direct measurement of gastric I.F. production is highly desirable. A report on such a case with this information is presently being prepared. We consider that the haematological and alimentary features of Dr. Riley's case could be attributed to jejunal diverticulosis alone with coexistent achlorhydria.

Cases of jejunal diverticulosis with progressive neurological damage occurring in the face of adequate vitamin-B₁₂ replacement such as he describes have been previously noted by Cooke and his colleagues¹ and by Badenoch *et al.*,² who also reported the post-mortem findings. Cooke and Smith³ have recently documented a similar sequence of events in cases of the sprue syndrome. Whether there is a disorder of vitamin-B₁₂ transport or utilization⁴ or malabsorption of some other nutrient awaits further elucidation.—We are, etc.,

Alcohol and the Law

SIR,—The article of Professor J. P. Payne and his colleagues (30 September, p. 819) is clearly a useful contribution in the struggle to get physiological variability accepted by laymen and our legal colleagues. However, I think it should be emphasized that many of his data relate to the high blood levels which were commonly seen in prosecutions under the 1962 and previous Acts and not to those around 100 mg./100 ml. that we anticipate encountering under the 1967 Act.

In our own data (1 April, p. 49) and in some subsequent experiments we have studied subjects with levels up to a maximum of 114 mg./100 ml. in the blood. At these levels we found urine blood ratios to vary just as much as Professor Payne, but our range was from 0.31 to 2.0, with a mean of just 1.0. Our experience was therefore that at these what we may call new levels urine is marginally more helpful to the accused than blood. Our lower values are of course due to the presence of urine in the bladder at the time drinking began.—I am, etc.,

East Ham Memorial
Hospital,
London E.7.

J. ENTICKNAP.

SIR,—Your leading article (30 September, p. 809) seems to me to miss one very fundamental point in the question of road deaths. According to A. J. P. Taylor,¹ road deaths in 1934 were 7,343 when there were 1.3 million cars on the road, while in 1963 they had actually fallen to 6,922 when there were 7.3 million cars on the road.

While alcohol is no doubt a factor in increasing the number of road deaths, I

believe I am right in saying that the increase since 1963 has been very small, and, bearing in mind the large number of relatively inexperienced drivers who have taken to the road, the figures are really not as unsatisfactory as they are made to appear.

We generally like medically to assess the problem which we are trying to solve before advising solutions for it, and it might be as well if the Ministry of Transport followed this precept.—I am, etc.,

ALEC WINGFIELD.

Doctors for Industry

SIR,—I am very surprised that your leading article "Doctors in Industry" (16 September, p. 692) does not mention the fundamental difference in aim between the present appointed factory doctor system and the proposed new A doctor scheme.

The appointed factory doctor system was started in 1833, in the days of child labour in our factories. In its day it was one of the most forward-looking experiments in social medicine and social care. The Factory Inspectorate and the medical profession have allowed this unique opportunity for helping juveniles to make the very difficult transition from school to work to sink to the level of a perfunctory physical examination and the signing of a book for a derisory fee. The Chief Medical Inspector has on more than one occasion stated publicly that "neither in detail nor in principle has the examination by the appointed factory doctor altered since its inception." Could there be any greater indictment of both Government department and medical profession? Between us we have failed to give any thought to the youth of the country in their urgent need for help to meet and understand the severe demands, both physical and mental, which modern society makes. Now we could recognize the sins of omission in the past and could build a new service to youth in industry in collaboration with the school health service, the youth employment officer, and the general practitioner. Instead we are to have 100 A doctors orientated towards adults and physical hazards in modern industry. This is no doubt a worthwhile aim in its own right, but to replace a service directed towards that section of the population most in need and most neglected by all the social services—namely, juveniles in industry—by a service orientated towards adults seems to me to be taking a large step backwards into the Victorian era.—I am, etc.,

Chipping Ongar,
Essex.

F. E. S. HATFIELD.

SIR,—Your leading article (16 September, p. 692) states: "If the School Medical Service issues a certificate of fitness for most leavers and a small group receives a 'disabled' certificate it may . . . make it easy for an unscrupulous employer to refuse all but the healthy school-leavers." You omit to point out that many large employers already do just this. The British banks, for

example, refuse to accept anyone for permanent employment unless he is a first-class life in the insurance sense.

A few years ago I saw a 22-year-old man with a blood pressure of 180/105 mm./Hg (with no cardiac enlargement, albuminuria, or retinal changes) who applied in turn to four banks, was accepted by all at interview, but later rejected following a medical examination. I wrote letters on his behalf to two of the banks condemning their deplorable attitude, but with no effect.—I am, etc.,

Farnham, Surrey.

JOHN W. TODD.

Antinuclear Factor

SIR,—In the leading article "Antinuclear Factor" (10 June, p. 654) you mentioned the interesting study by Pitkeathly and Taylor¹ in which they avoided the difficulty of distinguishing borderline cases of rheumatoid arthritis and systemic lupus erythematosus by considering all the cases with connective disorders as one group, subdivided exclusively on the presence or absence of antinuclear factors in the serum. In this connexion we would like to draw your attention to the article by Hijmans *et al.*² concluding that discrepancies in the finding of antinuclear factors are due not only to quantitative differences in the sensitivity of the techniques used but also to the presence of apparently qualitative differences between the antinuclear factors in different patients.

Secondly, we feel that our discovery of a new factor, the so-called "antiperinuclear factor," in the serum of patients with rheumatoid arthritis is also of importance in this connexion. Our study has subsequently been confirmed by others.³⁻⁵ The antiperinuclear factor (A.P.F.) seems to be specific for rheumatoid arthritis, and has until now only incidentally been found in systemic lupus erythematosus (see Table), thus differentiating the two groups of patients suffering from in other aspects probably related diseases in a rather astonishing way.

	Year	Disease	No. of Cases	No. of Cases A.P.F. Positive	% A.P.F. Positive
Nienhuis and Mandema ³	1964	R.A. S.L.E.	105 12	51 1*	48.5 8.3
Visconti <i>et al.</i> ⁴	1964	R.A. S.L.E.	37 12	29 1†	78.4 8.3
Cava <i>et al.</i> ⁵	1965	R.A. other dis.	48 No. not specified	37	77.1 1.7
del Giacco and Mazzei ⁷	1965	R.A. S.L.E.	20 5	9 0	45.0 —
Marmont <i>et al.</i> ⁸	1966	R.A. S.L.E.	100 28	51 1‡	51.0 3.5

* This patient, an 18-year-old female, had serious joint involvement, besides a number of other symptoms, and is now classified as definite R.A.

† This patient had, besides symptoms of malignant dermatomyositis, a polyarthritis from the rheumatoid type, stage IV.

‡ No specific data provided.

Considering the well-known clinical and immunological overlap between rheumatoid arthritis and systemic lupus erythematosus, the rare occurrence of the antiperinuclear factor in systemic lupus erythematosus is indeed a strong point in favour of its

specificity for rheumatoid arthritis.—We are, etc.,

Warming Blood

SIR,—Dr. Patrick J. Bennett's apparatus for warming blood (23 September, p. 787) is very interesting, but we should like to point out that results as good are available with simpler apparatus.

We have investigated the Baxter Laboratories disposable Plexitron coil as a heat exchanger in conjunction with a standard Grant Laboratories (J.B.I) 3-litre waterbath. This combination of apparatus fulfils Dr. Bennett's requirements in that it is convenient to handle, simple, and cheap (under £15).

The Plexitron coil is preformed and therefore does not have to be wound on to a carrier. It is also shorter, with an internal volume of approximately 50 ml., which eliminates large priming volumes. The heat-exchange properties are much better than drip-extension tubing. We would like to stress the importance of using tubing designed to be heated, since substances used in the manufacture of tubing may be released into the lumen when heated. It would appear advisable to check with the manufacturer if any other form of tubing is used.

A 3-litre waterbath gives a greater heat reservoir and enables several bottles of cold fluid to be passed through rapidly without a drastic fall in bath temperature. When an efficient heat exchanger is used the limitations of a small waterbath may become apparent.

We have conducted several experiments with this coil and waterbath and found that 1 pint (0.6 l.) of blood could be transfused in five minutes and the temperature raised from 6° C. to 35.3° C. If two coils were used in series a pint of blood could be passed in under two minutes, with an increase in temperature from 4° C. to 35.7° C. A prolonged transfusion of six pints of cold fluid in 27 minutes was raised from an average starting temperature of 12° C. to 34.4° C.

We heartily agree with Dr. Bennett's safety devices. Grant Laboratories can supply a temperature cut-out and locked control device for a fixed temperature setting if these are desired. We think that the use of known laboratory apparatus seen to be satisfactory for many years is an added benefit.—We are, etc.,

National Kidney Centre

SIR,—Your leading article (9 September, p. 631) on the closure of the National Kidney Centre does less than justice to the whole venture. It also shows a lack of appreciation of two facts. The first is that no patient is the property of one doctor, group of doctors, system of medicine, or, of course, the State. The second is that there is a basic defect in the N.H.S. plan for haemodialysis in that it is not home-orientated. It also seems that the author has insufficient experience of long-term home dialysis.

The National Kidney Centre has been of the highest significance for 30 patients in dire need, although obviously not for the Minister of Health (House of Commons, March 1967). The tragedy is that there would be no difficulty in dovetailing National Kidney Centre patients into the N.H.S. if the latter had initiated an expanding programme of home dialysis. It would have been better if instead of finding excuses for the actions and policy of the N.H.S. and poor reasons for the demise of the National Kidney Centre you had had some good word to say for a venture which, after all, has served to save the lives of some 30 people over the last nine months. This would have shown that you have the courage to speak up for advancement of thought rather than condone the conservatism and conventionality of the State machine.

We feel that you have overplayed the difficulties involved in treating intercurrent illness in patients on dialysis at home. Is it in fact certain that "complications [necessitating urgent admission to hospital is implied] [will occur] sooner or later"? For instance, the National Kidney Centre's experience (S. Shaldon personal communication) is that urgent hospitalization has been necessary on only two occasions in twenty patient-years of dialysis: an impressively low figure. Also it is often forgotten that when troubles do occur these patients have an advantage in that they have direct access to their systemic circulation, by way of shunts, for the administration of antibiotics (which it is quite possible for them or a relative to administer to themselves) and the collection of blood samples. Again shunt infection is not all that common in home dialysis and can usually be dealt with without hospitalization. If recannulation becomes necessary this is carried out as an outpatient procedure with no difficulty. Likewise, it is quite possible to deal with severe illness in the home, and one of us has experience of the successful cure of a classical lobar pneumonia at home while maintaining routine dialysis. This patient is now well and in steady employment.

If the N.H.S. had planned in time for home dialysis your criticism of such intercurrent illness prejudicing the treatment of an N.H.S. patient would in no way apply. We are not criticizing N.H.S. centres but the inexplicable reluctance of these centres to train their patients for home dialysis. Centre and home dialysis go hand in hand. A recent visit of one of us (M. H. F. C.) to British Columbia and the U.S.A. has shown that this is well recognized over there. It is the only way to treat the maximum number of patients with the available resources, and the rapid developments in renal transplantation make this policy more urgent, and the only humanitarian approach.

An equally strong argument in its favour, which would help your leader writer's problems, is of course that skilled hands (more rare and expensive than equipment) and equipment are freed to take on more patients in the centre. The National Kidney Centre could here have been of enormous help to the N.H.S., which could have used it to train its patients for home dialysis. Unfortunately the Ministry's decision has prevented this. Regional boards have had it within their power to refer patients to the

National Kidney Centre, but have unanimously decided not to make use of it.

One wonders what the personal decision of the members of these boards or even the Minister would have been if they had personally been confronted with a near relative dying of renal failure and unable to gain a place in the N.H.S. programme.

We believe that doctors exist to treat patients to the best of their ability from wherever they may come and however they may present. These patients are not the doctor's property. They cannot be blamed when treatment or a cure is not forthcoming from one source for seeking it from another, and we should applaud when private initiative provides an ethical and honest service where the N.H.S. has failed. We also believe with Mr. Medway (p. 680) that the closure of the National Kidney Centre would be a tragedy, and we strongly advocate the rapid development of an N.H.S. home dialysis programme and the more ready co-operation of all doctors in the treatment of their patients whether inside, outside, or half-way between any medical service or services.

Lastly, we would wish to put on record the thanks and admiration of ourselves and our patients with renal failure for the dedicated work done by the sponsors, staff, and the Director of the National Kidney Centre. We believe that this has been an inspired medical, scientific, and humanitarian venture.—We are, etc.,

M. H. F. COIGLEY.

I. R. McWHINNEY.

Use of Thorotrast

SIR,—Thorotrast is the subject of an approved new drug application under the provisions of the U.S. Food, Drug and Cosmetic Act. As you know, this means, in effect, that the Food and Drug Administration has approved the drug for use by the medical profession in the U.S.A. only under certain limited conditions, and that it is safe and effective only in those conditions. The label, labelling, and sales agreement which must accompany this product when sold in the United States set forth in precise detail the conditions of use which the Food and Drug Administration has approved for the drug. The authorized uses are closely restricted and the product may be administered only under the supervision of certified radiologists.

The article by Drs. A. O. Langlands and E. R. D. Williamson (22 July, p. 206) indicates that Thorotrast may be used for conditions other than those specified in the literature enclosed with each vial. This would be unwise, since not only is such use unauthorized in the U.S.A. but it could indeed seriously jeopardize the health and welfare of persons to whom it is administered. The drug must be used only in those conditions where the life expectancy is definitely short. Thorotrast is a valuable research item and is used in our most prominent research institutions to follow the effects of chemotherapeutic agents in malignant diseases of the liver and malignant cysts of the brain. Indeed, no other uses have been authorized.—I am, etc.,

Insulin Allergy

SIR,—We read with interest the case report by Drs. R. Cockel and Sheila Mann (16 September, p. 722) in which they described the value of the simultaneous administration of insulin and hydrocortisone in the management of insulin hypersensitivity phenomena, both local and systemic. One of us reported a series of similar observations with reference to local hypersensitivity phenomena at the Fourth International Diabetes Meeting in 1961,¹ and in subsequent publications we have investigated the immune mechanisms in such cases.^{2,3} The subject was also discussed at the 1963 meeting of the British Diabetic Association in Dublin.

The suggestion that the "allergic" response to insulin is due solely to impurities in the preparation seems unlikely in view of the abundant evidence now available of the development of antibodies to insulin using highly purified preparations.⁴ We have also demonstrated that the local weal and flare response to insulin, which is the local form of type I allergic reaction under discussion, is due to immune globulins which distinguish between highly purified recrystallized beef and pork insulins. The experience of Jorpes,⁵ who obtained his 300 cases of insulin hypersensitivity during the last war, when purified insulin preparations were not available, can hardly be compared with experience gained from current insulin preparations.—We are, etc.,

Obstetric Complications and School Performance

SIR,—Perhaps I might be allowed to comment on the extremely interesting and valuable report by Drs. D. J. P. Barker and J. H. Edwards on obstetric complications and school performance (16 September, p. 695). It is said that the results obtained did not conform to my study,¹ and, although not referred to, a further study reported in 1967.² While this would appear to be fair comment in view of the comparatively large number of children available and detailed analysis of the Birmingham study, I would suggest that the two reports are not really comparable.

My report purported to relate intelligence in children who had had a normal antenatal and obstetric history. Intelligence was taken to be that quantum readily understood by the teacher who had had some years of experience with the child. That this is not related exactly to verbal reasoning scores assessed by the classic 11-plus examination method is, as the protagonists of the comprehensive school are only too ready to point out, now fully accepted—for example, in my own

One 100 mg. capsule in the early evening allows the patient to relax in the leisure hours—sleep naturally—and face up to the difficulties of the day

Equipose is not a barbiturate, neither is it a hypnotic. It is a psycho-relaxant with a calming action which is precise and localized. Equipose acts almost exclusively on the hypothalamus where the basic emotions of fear, anger and agitation are mediated. There is little or no 'drug trespass' into the cerebral or spinal cord areas.

This explains why treatment with Equipose is free from euphoria and habituation,^{1,2} withdrawal reactions,² and drug-induced depression³.

Equipose is rapidly active, and a single dose is effective for up to 12 hours. Full information is available on request.

area a comprehensive school claims that last year the top third of the year examination results showed that 48% of them were 11-plus failures.

Our definition of "term" is in my submission significantly different; theirs being 38-41 weeks of gestation and mine being as near as possible to 40 weeks. My contention is that a higher intelligence is obtained in normal children born during weeks of gestation 37, 38, 39, than in those born during weeks of gestation 41, 42, 43, and Dr. Barker's Table IV, although it presumably includes children whom he shows to be at risk, would, I have thought, certainly not have failed to confirm my own results.

As regards his rather unexpected findings on forceps delivery, one wonders if the type of anaesthesia employed might not be a potent factor, as with the adoption of pudendal block as routine for forceps instead of inhalation anaesthesia it is most noticeable that the "shocked baby" has become something of a rarity and the "blue baby" even more so. While I would entirely agree with the comments on "sib control" in a series like the Birmingham one, I would suggest that this is not so important in so tight a controlled series as my own.

In conclusion may I say that investigations of this sort are still lamentably rare, on a subject as important as the possibility of raising the level of intelligence with the aid of fully considered obstetric manoeuvres, and Drs. Barker and Edwards will have done a real service in this respect if they have taught us that term is 38-41 weeks of gestation, and not 40 weeks or shortly after.—I am, etc.,

Folate Deficiency in the Elderly

SIR,—I was interested in Dr. A. J. Gardner's comments concerning folate deficiency in the elderly (12 August, p. 436). When carrying out precise clinical investigations into folate deficiency states one should always aim at as large a degree of accuracy as possible, and it is particularly at the lower limits of "normal" serum folate levels in the elderly that I question that the test is accurate enough by itself for "practical purposes." I think that liver biopsies are only justified in exceptional circumstances as an aid to the diagnosis of folate deficiency in the elderly, and that red cell folate assays are, from the patient's point of view at least, a more satisfactory test.

Naturally there is a correlation between red cell folate levels and serum folate levels, but when one is dealing in clinical practice with individual patients it has been demonstrated that there is a very large range of red cell folate levels for any individual serum folate reading. Lowenstein *et al.*¹ showed that for a serum folate level of, say, 3.5 $\mu\text{g./100 ml.}$ the red cell folate range was between 100 and 400 $\mu\text{g./100 ml.}$ Cooper and Lowenstein² showed that for any serum folate level of 3.5 $\mu\text{g./100 ml.}$ the red cell folate range was between 50 and 400 $\mu\text{g./100 ml.}$, and Hoffbrand *et al.*³ showed that "at any given folate level in the borderline range there was a wide variation in the red cell folate level," varying from 100 $\mu\text{g./100 ml.}$ to

levels within the "normal range." Scatter diagrams in all three papers mentioned elaborate this point in detail. Moreover, Victor Herbert,⁴ in his classical work on experimental nutritional deficiency in man, showed that serum folate levels can rise transiently after folate replenishment within an hour or two following four and a half months of folate deprivation.

Folate levels in district hospitals are often difficult to obtain, but perhaps in the elderly at any rate, where serum folate levels below 6 $\mu\text{g./100 ml.}$ are relatively common, it would be a great aid to accurate diagnosis to be able to obtain red cell folate estimations in addition.—I am, etc.,

Admirable Drug

SIR,—It appears likely that each civilization demands a drug. Tobacco is the most admirable of all. It soothes and composes, it makes for better temper, it keeps men in the chimney-corner, it stimulates thought.

If banned, whence should come the £1,000m. of lost revenue? It does not need an economist to point out that the release of this amount of spending power could not be allowed and that a similar amount would have to be claimed back by other taxes. If tobacco goes then drink and gambling must follow, for these two are home breakers and in anything but strict moderation can and do bring ruin. Not a single newspaper could survive the loss of advertising entailed. Is this of no interest to doctors?

As we get older nowadays we get more and more to fear the onset of helplessness and dependence—so here is a final beneficence of the divine weed. It clears us off before we begin to clutter up the earth.

It is the business of the B.M.J. to advertise as widely as possible the connexion between disease and tobacco. It has no business whatever to try to influence people's private decisions or to seek arbitrary extension of miserable old age by decree.—I am, etc.,

London N.W.4.

R. W. COCKSHUT.

Menace of Smoking

SIR,—In your informative leading article (23 September, p. 753) you say, "... it [smoking] is not, like the epidemics, a communicable disease—except by example." Of course it is. And it's not merely epidemic, it's pandemic. About half the adult population of western countries and vast numbers in eastern countries suffer from it. It is not communicated by the "old fashioned" method of micro-organisms but by something just as deadly—lies, and of course example, as you say—that is, "psychological infection." The basic lies are two:

(1) That tobacco is a luxury. In fact tobacco is a drug. Its pharmacological and toxic actions are described in all standard

textbooks on pharmacology. But it is sold in shops other than chemists. And it is heavily taxed—treated in fact like a luxury.

(2) That smoking is a habit. There is a habit factor in smoking, but essentially it is a means of taking nicotine—just as opium-smoking is a means of taking morphine.¹ Anyone who repeatedly takes a drug as strong as nicotine is addicted to that drug and is a drug addict. Most diseases are poisonings. All smokers suffer from nicotine poisoning—according to how heavily they smoke, and nicotine poisoning is a disease no less than lead poisoning, though the symptoms are more acceptable (to the smokers). The main symptoms are: recurrent sore throat and cough, and undue fatigability and depression (after depression). But smokers tend to repress or make light of the cause of their symptoms because of the strength of their craving for tobacco.

Your leading article also affirms that smoking "is surely the greatest menace to the public health of our time." Yet smoking is a curable and preventable disease. It is no more difficult to prevent than opium-smoking.

What is now needed is vigorous national health education: frequent talks, mainly short and sharp, with no punches pulled, on radio and television at peak times. We should press for this, and, should the Government veto or sabotage this campaign, we should go on-strike; deal with emergency cases only. How refreshing, a strike for something other than pay and conditions.—I am, etc.,

Malta.

Headlight Glare

SIR,—The elimination of headlight glare by covering lights with polaroid film and drivers' eyes with film with its plane of polarization at right angles to the first, as recommended by Dr. S. J. Lines (30 September, p. 867), would almost certainly prevent a number of fatal and other accidents. However, his suggestion of setting the plane of polarization at 45° from the vertical is not necessarily the best solution.

Many motorists already possess polaroid spectacles with the transmission plane of polarization (direction of the electrical vector) set vertically so as to eliminate glare from the horizontally polarized light reflected from road surfaces, especially when wet. This advantage of existing polaroid spectacles, visors, or windscreens could be retained if headlights were all polarized horizontally.

The advantage of making the planes of polarization of a driver's own headlights and his glasses or visor compatible with one another is not as great as Dr. Lines assumes, since most of the light by which the driver views objects ahead would be depolarized by multiple reflections. The one important exception is "cat's eyes" and other reflecting signs, and the apparent intensity of these might be considerably reduced by the horizontal-vertical system. The problem is thus one of balancing advantages and disadvantages, and could easily be settled by simple practical trials. Polaroid film transmits a little unpolarized light at each end of the spectrum, and bright lights such as car headlights would possibly be sufficiently obvious

without any deliberate limitation of polarization, appearing as a deep reddish purple colour.

The question of cost would no doubt be raised. Most optical devices incorporating polaroid film are very expensive, but the film itself is relatively cheap and could probably become cheaper still if millions of mass-produced devices were needed—almost certainly much cheaper than many compulsory safety features already incorporated in cars.—I am, etc.,

Court Lees School

SIR,—I would endorse Dr. J. H. Lancaster's plea (2 September, p. 619) for an elucidation of the points he raises, especially in regard to the accuracy of the colour photographs.

In a B.B.C. T.V. programme on 18 August, when this matter was discussed, a photograph which I believe was one of those used in evidence was shown briefly. It was in monochrome, but its appearance immediately roused my suspicions for two reasons. The first was that the marks were equally apparent on both right and left buttocks and the second that they were equally distributed across the buttocks from the top of the natal cleft to the upper part of the thighs.

Unless that boy was caned by an ambidextrous individual, operating first from his right side and then from his left, who had taken especial care to distribute the strokes at regular intervals from the sacral region to the upper part of the thighs, I would beg leave to doubt the authenticity of that picture.—I am, etc.,

Harrow, Middx. J. B. WRATHALL ROWE.

Portable Pharmacy

SIR,—I have a book of instructions sold with a portable pharmacy similar to those mentioned by Dr. P. W. Mathew (3 June, p. 641) and Dr. F. N. L. Poynter (24 June, p. 843), which is of added interest, as it contains a catalogue of these chests issued in 1814. They vary from the family dispensary at £20 8s. to the lady's dispensary at £5 10s. The country clergyman's dispensary at £9 5s. is "made on a very cheap plan, and supplied with black bottles," while the vestry medicine chest at £1 10s. 6d. "has been found very serviceable in cases of fainting or hysteric fits which often occur during divine service."

Chests are listed for the use of travellers on the Continent and in the tropics, and at £32 10s. the sea medicine chest is provided for Navy surgeons and captains of merchantmen. This latter chest, in addition to the usual formidable purges, contains a useful supply of mercury.—I am, etc.,

Southall, Middx.

R. J. RABETT.

Visible Alternatives

SIR,—I refer to your leading article (7 October, p. 6). Already 19 years have been futilely wasted on committees and reports. How much longer is the profession going to dither?

While the delusion exists that it is a health service there is no hope. Once it is recognized as an ill-health service the alternative of a health service is or should be obvious, and its organization reasonably clear. Being slow and dim-witted, it took me several years to fully recognize this.—I am, etc.,

Rochdale,
Lancs.

L. McASKIE.

Enticing the Emigrants Home Again

SIR,—We are told the Minister of Health is to launch a campaign to coax the emigrant doctors to return to the fold.¹

If this intention is genuine, and not just a gimmick for political window-dressing, then I suggest one of the first things he does is to rescind the wretched "break" clause in the seniority award regulations whereby any general practitioner who has a break of more than three months automatically forfeits his seniority awards.

Many of the general practitioners who have emigrated are in the 40–50 age group; contrary to popular opinion, they are by no means all young ex-hospital staff newly qualified. These older men would all qualify sooner or later for seniority awards if this pernicious "break" clause were to be removed. What better example of his good faith could the Minister make to these "erring" sheep than to restore their lost eligibility for seniority awards they rightly deserve?

I really cannot imagine how the older general practitioners are to be enticed back if they have to endure the insult (for that is what this idiotic clause really is) of going to the bottom of the queue again for their seniority awards. A large number of general practitioners have forfeited their awards because of this arbitrary and vicious penalty; and it astonishes me that more of a fuss has not been made about it.

I have a letter before me from one general practitioner who was foolish enough to go to Zambia under the scheme for secondment of doctors in the N.H.S. to underdeveloped territories. He was given to understand he would suffer no loss of pension rights. Now, after returning, he has been told that because of his absence he has forfeited any seniority award. What a cynical decision, and how very unfair and un-British this sort of political opportunism has become.

Never has a respectable profession been treated so cynically and so disgustingly. My advice to would-be returning doctors is to clear up this business of forfeited awards *before* they are persuaded to return home again. Otherwise they may find themselves in for an unpleasant surprise when it is too late to change their minds again.—I am, etc.,

Miserable Conditions

SIR,—As general practitioners are insidiously and relentlessly being cornered by the present Government into eventually having to accept a salaried service, we are rapidly approaching cross-roads. Some general

practitioners are so fed up that they themselves would opt for a salaried service as the least of the N.H.S. evils, so gaining regular hours and holidays, a supply of locums and staff, etc.

It continues to amaze me that we sit quietly by accepting new restrictions, regulations, and frustrations one after the other. Patients' signatures for immunizations, maternity care, and night visits are just three of these which come immediately to mind. Soon, no doubt, patients will have to sign that they have received the right and proper treatment and prescriptions as demanded.

One outstanding anomaly of this free N.H.S. is the example of specialist referral. I am not allowed to issue an E.C.10* to a private patient. Yet if a patient on my list elects to pay a consultant for certain privileges—for example, to save waiting time, to have a more lengthy consultation, or even to guarantee that he will be seen only by the consultant to whom he has been referred—he may then receive treatment on an E.C.10 via the general practitioner. This is quite ridiculous and most unjust. Of course, I may refuse to issue an E.C.10, but as long as I am being paid per caput as a basic income I will agree to do so or risk losing a substantial number of patients who are, in ever-increasing numbers, insuring themselves against private consultations.

Let us hope that in the foreseeable future either the general practitioners will unite against these miserable conditions of service or that the situation will change so that we can limit our lists (so giving a better service) and not toe the line, which we all at present do whether we like it or not.—I am, etc.,

Leeds.

G. R. ADDLESTONE.

How Many Old People?

SIR,—For pensioners over 65 on general practitioners' lists there is an extra capitation fee. Accordingly the executive council, which keeps the accounts, is able to state how many such persons there are in a given locality. In this area the executive council has kindly supplied the numbers of old people and just where they are situated. This is most helpful in planning hospital and geriatric services.

The object of this letter is to suggest to some of your readers this way of arriving at an accurate estimation of the number of old people.—I am, etc.,

St. Mary's Hospital,
Colchester, Essex.

K. HAZELL.

Points from Letters

Sales Promotion

Dr. W. M. E. TOPPING (Cheadle, Lancs) writes: I would like to assure Dr. J. R. Caldwell (16 September, p. 741) that he is not alone in noticing the great increase in numbers of representatives and also the frequency of their visits. So great was the interference with my work that I took the step that Dr. Caldwell contemplates about nine months ago. . . . The drug companies are their own worst enemies in this business, and I took the trouble to see each representative one last time to ask him to inform his company why I was doing this.

Until a great many more doctors take this step they will be increasingly pestered. It is like stopping smoking: it is infinitely easier to stop than to cut down.

Obituary Notices

J. B. McDougall, C.B.E., M.D., F.R.C.P.ED., F.R.C.P.GLASG., F.R.S.ED.

Dr. J. B. McDougall, a distinguished phthisiologist, for many years medical director of the British Legion Village Settlement at Preston Hall, Kent, and for some time chief medical adviser in tuberculosis to the World Health Organization, died in Athens on 30 September, aged 76.

John Bowes McDougall, son of Allan McDougall, of Greenock, was born on 5 December 1890. He was an able scholar at Greenock Academy, and carried off many prizes both at school and at Glasgow University, where he graduated M.B., Ch.B. in 1914. In 1916 he was awarded the M.D. with commendation, and was elected M.R.C.P.Ed. in 1919. In the same year he was elected Fellow of the Royal College (then Faculty) of Physicians and Surgeons of Glasgow. In 1928 he was elected to the Fellowship of the Royal College of Physicians of Edinburgh, and later in the same year to the Fellowship of the Royal Society of Edinburgh. In 1943 he was appointed C.B.E., and in 1964 the Royal College of Physicians and Surgeons of Glasgow elected him to the Fellowship of the College. These many academic achievements were accompanied by prowess in athletics and games, and he was one of the few who represented Scotland in international rugby, both before and after the first world war. He played for Scotland against France in 1914 and again in 1921, against Ireland in 1914, and against England in 1922.

From the earliest days of his professional career he was interested in tuberculosis, and soon after graduating he held appointments in tuberculosis hospitals and clinics in Manchester and Stoke-on-Trent. During the first world war he joined the R.A.M.C., attaining the rank of major and the command of No. 30 General Hospital at Calais. This administrative experience served him in good stead in his subsequent appointments. After demobilization he became medical superintendent of the Wooley Sanatorium, Northumberland, and it was here that he first showed his keen interest in the rehabilitation of tuberculous patients and the need to provide them with remunerative employment and eventually a career which would enable them to become again useful citizens. He became associated with Dr. (later Sir) Pendrill Varrier-Jones, who had by then established industries and a village settlement at Papworth. There were at that time many tuberculous ex-Servicemen, and the British Legion came to their help by sponsoring and financing a scheme for industries and a settlement at Preston Hall, near Maidstone. McDougall was the obvious choice for the post of medical director of this project. From 1925 he devoted himself unsparingly to the development of this institution, which by 1944 had grown into a great industrial concern, doing much Government work in the printing and woodwork departments, as well as providing a large number of houses and hostels for tuberculous ex-Service men and women, and their families. McDougall encouraged the British Legion to devote more attention and money to tuberculous ex-Service men and

women, and persuaded them to open Douglas House, Bournemouth, for the treatment and employment of elderly male patients; and Nayland Sanatorium, Colchester, for ex-Service women.

After studying tuberculosis in Canada, the U.S.A., France, and Germany, he introduced tomography in chest examinations, and installed the first of such units in this country at Preston Hall Hospital.

In 1944 he was asked by U.N.R.R.A. to advise on tuberculosis problems, and from this appointment he proceeded to be chief tuberculosis adviser to the World Health Organization. He travelled widely, and after leaving Geneva he went to Cairo, where he established a tuberculosis college for post-graduate tuition in all aspects of the disease. He contributed largely to tuberculosis literature, and was a prominent member of the then National Association for the Prevention of Tuberculosis (now the Chest and Heart Association) and the Joint Tuberculosis Council, of which he was secretary for many years.

On retirement he lived in Athens, where he derived much happiness from the good fellowship of the Greek people and the warm pleasant climate. He did not enjoy very good health in later years, and was much handicapped by having to have a leg amputated some five years ago. This was a great strain on a person with such unbounded energy, for McDougall never did anything by halves. While he was organizing and developing Preston Hall he studied music intensely, and obtained the A.R.C.M. and the L.R.A.M. In addition he wrote many books; some on tuberculosis, of which the *Global Study of Social Pathology* has become a standard work of reference. Other publications of his were about small livestock, in which he was always interested, and he became a leading authority on angora rabbits.

McDougall had a wide circle of friends, both in Scotland and in England, and his forthright, fearless, and valuable advice on the administrative and clinical problems of tuberculosis was widely sought and always willingly given. The passing of McDougall removes from the world one of the greatest veterans of tuberculosis medicine of this country, and all who knew him will have memories of his impressive personality for many years to come.

He leaves a widow and two sons, one of whom is a physician. We extend our deep sympathy to them in their great loss.—F. H.

S. B. RADLEY, M.B., B.S., F.R.C.S.

Dr. S. B. Radley, emeritus surgeon, Newark Hospital, died at his home in Newark-on-Trent, Nottinghamshire, on 13 September. He was 78.

Sidney Bertram Radley was born on 18 September 1888, and was educated at Manchester University and St. Bartholomew's

Hospital, London. He graduated M.B., B.S., with honours and distinction in medicine, from London University in 1911, and in the same year he graduated from Victoria University, Manchester, with second-class honours. After early house appointments in London and Manchester he took the Conjoint diploma in 1913 and the F.R.C.S. in the same year. During the first world war he joined the R.A.M.C., serving overseas as surgeon specialist. After demobilization he settled in Newark, and in addition to his appointment as honorary surgeon at Newark Hospital he was also in practice as a family doctor. In the second world war he was the senior surgeon at Newark Hospital, and spent many nights at the hospital operating on air raid and Bomber Command casualties.

A member of the British Medical Association, he was a representative at the Annual Meetings from 1942 to 1945, and again from 1948 to 1954, and was president of the Nottingham Branch in 1953-4. Among his hobbies were golf, archaeology, and ornithology. He retired in 1955.

From my first meeting with Sidney Radley in 1926, when I came to Newark as a young general practitioner, I felt that he was a man that I could trust and go to in any kind of trouble. This impression never altered, and must be shared by many of his colleagues and friends. He had a sense of humour all his own, and nearly always illustrated his points with some very appropriate anecdote fitting to the occasion. He was a fine man and a fine doctor.—A. M. D.

B. THOMAS, M.B., B.S., F.R.C.S.ED.

Dr. B. Thomas, formerly honorary surgeon at the General Hospital, Aberdare, died on 4 September. He was 72.

Benjamin Thomas, son of Dr. Ieuan Thomas, was born on 8 July 1895, and was educated at Epsom College and St. Mary's Hospital, London, qualifying with the Conjoint diploma in 1917. He served as a medical officer in the Royal Navy during the first world war, and after demobilization graduated M.B., B.S. in 1919. He held house appointments at St. Mary's Hospital and the Derbyshire Royal Infirmary before taking over his father's practice at Hirwaun, Glamorgan. Elected F.R.C.S.ED. in 1920, he became honorary surgeon at the General Hospital, Aberdare. He was the first chairman of the medical staff committee, and became senior hospital medical officer at Aberdare General Hospital when the National Health Service was introduced. He was also a member of the hospital management committee and a member of the local medical committees for Glamorgan and for Brecon. A member of the British Medical Association, he was chairman of the North Glamorgan and Brecknock Division in 1950-1. He retired some 10 years ago and made his home in the Penarth district.

As a general-practitioner surgeon he was held in high esteem by patients and colleagues, and will be remembered as a man

capable of wise decisions and sound judgement. These qualities were also much appreciated in his service to the community as deputy coroner for South Breconshire and as a justice of the peace for the county of Glamorgan.

We extend our sympathy to his widow and to his son, now an electrical engineer in Rhodesia.—J. E. T.

C. M. BARKER, M.A., M.B., B.CH.

Dr. C. M. Barker, a familiar figure to many generations of psychiatrists and psychotherapists, died on 11 September after a short illness. He was 76.

Culver Maynard Barker was born in England on 4 March 1891, but spent his early life in British Columbia. After working as an engineering apprentice for the building of the railway in the Klondike he returned to Britain during the first world war with the 1st Battalion of the Engineers of the Second Division and saw active service in France. After demobilization he decided to stay in Britain in order to train for one of the professions. He studied at Pembroke College, Cambridge, and at University College, London, qualifying in 1926 with the Conjoint diploma, after which he held house appointments at the Royal Northern Hospital and Manor House Hospital, London.

In 1927 Dr. Barker met C. G. Jung. It was a turning-point in his life. He arranged to study with Jung in Zurich throughout the following academic year. On returning to Britain he entered psychiatry by becoming medical officer to the observation ward at St. Peter's Hospital, Whitechapel, where Dr. E. Mapother, superintendent of the Maudsley Hospital, was the visiting psychiatrist. In those days no treatment or aftercare (other than referral to a mental hospital) was provided by observation wards. But Dr. Barker, inspired by Jung's work with psychotic and borderline psychotic cases in the Burghölzli Hospital, Zurich, introduced psychotherapy into what was then regarded as a most unpromising field. For several years he conducted an unofficial outpatient clinic, obtaining patients from among those who were discharged from the observation ward and from other departments of the hospital. The conditions were primitive and the work was often regarded with suspicion. But Dr. Barker persisted in it and in later years it was with some pleasure that he recounted how it had been in the East End of London that he first tested and proved the efficacy of Jung's method of psychotherapy. He received some official acknowledgement of this work when an account of it was included in a London County Council report in 1937. In the same year he completed the M.B., B.Ch., and left Whitechapel to take up a post at the Cassel Hospital; combining this with private practice and a clinical assistantship at University College Hospital. At the same time he was able to find expression for his interest in children by joining the staff of the Institute of Child Psychology, where he was consultant psychotherapist for many years.

During the second world war Dr. Barker, like many of his colleagues, became interested in the new physical methods of treatment which were being introduced into our mental hospitals at that time. Having learned the technique of administering E.C.T. in a large

hospital, he became one of the first psychiatrists to acquire his own apparatus and use it in his private practice, where he often combined it with psychotherapy. After the war he returned to a more exclusively psychotherapeutic practice. He was able to renew his contact with Jung and with his many other colleagues and friends in Zurich. He became a frequent visitor to that city, and he gave many lectures in the C. G. Jung Institute. Dr. Barker was an indefatigable worker up to the time of his death; and he was a keen participant in the affairs of various societies concerned with psychotherapy, in particular the Society of Analytical Psychology, of which he was a founder member.

Barker was, at one and the same time, a most ordinary and a most unusual person. Many would count him as a familiar friend and colleague, but few knew him at all intimately: he hardly ever spoke of himself. He was dedicated to his work, for which he had exceptional gifts, though he did not always do himself justice in this respect in his public utterances. He seemed almost totally uninterested in power and prestige; and, although not without shrewdness, he had a most kindly and philosophical outlook on life. Culver Barker occupied a unique place in the lives of many of us and he will be very much missed. He is survived by his widow.—R. L. M.

C. B. C. writes: Dr. Culver M. Barker was one of my closest friends for 40 years. He was kind, wise, and enthusiastic. He referred everything to its roots. He was a real lover of nature, and keen on getting back to nature. He was always talking about his consciousness as part of the universal consciousness of all living things. Thus he was able to act as guide and father to a large circle of people who were lonely and found life too much for them. He will be sadly missed.

F. O. WALKER, M.R.C.S., L.R.C.P. D.P.M., D.O.

Mr. F. O. Walker, who was formerly consultant ophthalmic surgeon to the Dartford Group of Hospitals and Queen Mary's Hospital, Sidcup, died in Joyce Green Hospital on 21 September. He was 73.

Frederick Oliver Walker was born in London on 10 November 1893. Throughout the first world war he served in the ranks in the R.A.M.C. at casualty clearing stations in France. During his service, assisted by a young medical officer and encouraged by his commanding officer, he matriculated. After demobilization in 1919 he entered the Middlesex Hospital Medical School, and qualified with the Conjoint diploma in 1924. He entered the mental hospital service, working at Colney Hatch, Horton, Hanwell, and eventually at Bexley. He took the D.P.M. in 1928. It was at Bexley that he developed his interest in ophthalmology and began studying at the Royal Ophthalmic Hospital, taking in 1933 the diploma in ophthalmology. About 1929 opportunities for engaging in ophthalmic surgery developed in Dartford, and so Mr. Walker resigned from the mental hospital service and devoted himself to this specialty. During this time his services were utilized by the local hospitals—

West Hill, Joyce Green, and the Southern Hospital at Dartford, and Queen Mary's Hospital at Sidcup; and he also became ophthalmic surgeon to the Battersea General Hospital.

During the second world war Mr. Walker's services were in great demand, and he was unsparing in his efforts on behalf of the injured. In 1948 he was appointed consultant ophthalmic surgeon to Queen Mary's Hospital, Sidcup, and to the Dartford group of hospitals, and he maintained his private practice, centred on Dartford, where he lived. He retired in 1958, and was appointed honorary consultant surgeon to the hospitals he had served. He continued his own consultative work, however, up to the time of his death.

A member of the British Medical Association, he was representative at the Annual Meeting in 1953, and chairman of the Dartford Division in 1953-4. He was not intimately known by many, but he gained the good will, the loyalty, and confidence of his patients and colleagues. He lived among those for whom and with whom he worked, and was well known in his professional and private capacity, and was trusted in both.

He leaves a widow and three sons.—T. S. C.

W. L. WINSLOW SMITH, M.C., M.B. B.CH., B.A.O.

Dr. W. L. Winslow Smith, a well known general practitioner of East Horsley, Surrey, died on 14 September while on holiday at Kirkcudbright. He was 71.

William Leslie Winslow Smith was born at Blackrock, County Dublin, on 10 February 1896. He was educated at Mountjoy School, Dublin, and entered Trinity College, Dublin, in 1912. He studied mathematics and was elected Scholar of the House in 1914. He volunteered soon after the outbreak of the first world war, and served with the Royal Artillery in France, being awarded the Military Cross, and was twice mentioned in dispatches. During the latter part of his service he was captain and adjutant. After demobilization he returned to Dublin University in 1919, taking his B.A. in 1920 and qualifying M.B., B.Ch., B.A.O. in 1923. He was captain of the Dublin University Rugby Club for two years after the war, and was also an outstanding athlete, creating a record at Trinity College, Dublin, for throwing the discus. He went to Ceylon in 1924, where he spent six years as medical officer of the Dickoya District planters' association. On returning to England he served as house-surgeon at the Royal Victoria and West Hants Hospital, Bournemouth. He came to East Horsley in 1931, and very soon became a successful general practitioner. He was appointed district medical officer and vaccination officer for the Horsley and Clandon districts.

Dr. Winslow Smith was a family doctor who took a very personal interest in all his patients. In the days before the comprehensive National Health Service, he attended less fortunate patients for nominal fees, and as often as not for love, in the highest tradition of the medical profession. He was an active member of the British Medical Association, serving for many years on the executive

committee of the Guildford Division, also on the Surrey Branch Council, and was chairman of the Guildford Division in 1950-1.

After a life of strenuous service he had a serious illness in 1961, and was obliged to retire from National Health Service practice to live a quiet life. During these last years those who visited him either socially or for medical advice were invariably struck by his cheerfulness, his patience, and his concern for others. No one ever heard him complain of his own pains or disabilities.

In 1933 he married Marjorie Florence, daughter of the late Mr. J. H. Cleland, of Richmond. She was a tremendous support to him, particularly in recent years of suffering and relative inactivity. Their many friends in the profession will offer her their deep sympathy.—C. P. W.

M. G. GARRY, L.R.C.P.&S.I., L.M.

Dr. M. G. Garry, medical officer of health for Formby, Lancashire, died in hospital on 17 September after a short illness. He was 80.

Michael Gerald Garry was born in Ennis in 1887, and qualified with the Conjoint diploma of the Royal College of Surgeons in Ireland in 1912. He later became assistant master at the Coombe Lying-in Hospital, Dublin. After several hospital appointments he took up general practice in Co. Clare. In 1926, however, after the death of his infant son, he came to England and joined the late Dr. A. C. Wilson and Dr. E. L. Roberts in practice at Formby, Lancashire, where he later became medical officer of health, an appointment he held until his death.

Michael Garry had great personality and clinical flair, reinforced by deep sympathy and unlimited patience. He was by nature a rebel, always prepared to cut the red tape of officialdom if by so doing he could benefit a patient, and there are very many who will mourn his death. But it was as a sportsman that he was known to a much wider public. Between 1908 and 1911 he was capped for Ireland seven times against England, Scotland, Wales, and France, and it was seldom that he missed seeing the England-Ireland rugby international. He had the Irishman's love of racing, and for years was medical officer to Aintree racecourse, where many of the leading National Hunt jockeys came under his care. Golf took up much of his spare time, and he was an ex-captain of the Formby golf club.

He was married twice, and to his widow, Cynthia, and his three daughters we extend deep sympathy in their loss.—E. L. R.

LEONARD COLEBROOK, D.S.C.

M.B., B.S., F.R.C.S., F.R.C.O.G., F.R.S.

B. W. writes: As one who worked as a resident at Queen Charlotte's Hospital in the days of the Isolation Block, and who had much help from him in one of the early trials of the sulphonamides, I should like to pay my tribute to the memory of this great man, known affectionately to all as "Coli" (obituary, 7 October, p. 59). Although always very modest about his success, his results came from a prepared mind which had studied deeply the problem of infection, and from his training with Almoth Wright, whose biographer he was. Wright's main claim to fame may well rest on the work

of his great disciples, Fleming and Colebrook. No aspect of obstetrics escaped Colebrook's attention. He would spend time and effort instructing a house-surgeon in cross-matching, when this was a "do it yourself" procedure. But his vision ranged far beyond the laboratory. His experience with burns led him into his successful campaign for non-inflammable clothing. His principle was, "If preventable, why not prevented," and present-day obstetricians who have never seen puerperal sepsis in full flood should remember that the long experience of this great worker with infection in peace and two wars never made him subscribe to the easy but dangerous view that the age of infection is past.

F. H. K. G. writes: I was privileged, as secretary of the M.R.C. War Wounds Committee, to see much of Dr. Colebrook (obituary, 7 October, p. 59) during the second world war, and I should like to pay tribute to his industry, his humanity, and his modesty. A pioneer in the clinical trial of sulphonamides against streptococcal infections, he played an important part in establishing the role of these drugs, and later of penicillin in the control of infection in wounds and burns, as well as in devising other methods to prevent hospital cross-infection of injured surfaces. Although he had no children himself he was devoted to children, and the high incidence of burns due to domestic accidents among children admitted to his units at Glasgow and Birmingham caused him great distress. After his retirement he devoted much of his energy to a successful campaign for the improvement of safety standards for gas and electric fires and to encouragement of the use of fireproof clothing for children.

G. S. W. writes: Leonard Colebrook's friends will be saddened by his sudden, though not unexpected, death (obituary, 7 October, p. 59). He was one of those happy mortals who command both respect and affection. He had a most endearing nature. Modest in the extreme about his scientific attainments, loyal and devoted to his chief, lively, humorous, and entertaining as a companion, brave and uncomplaining in face of the adversities that finally overcame him, he will long be remembered by his numerous and varied colleagues. To his wife, Vera, who tended him so faithfully during the latter years of his life, all who knew her will extend their sympathy.

Sir JAMES LEARMONTH, K.C.V.O.

C.B.E., LL.D., M.D., CH.M., F.R.C.S.

F.R.C.S.ED., F.R.A.C.S., F.A.C.S.

F.R.F.P.S.GLASG.

R. L. R. writes: As a teacher James Learmonth (obituary, 7 October, p. 58) was superb, and the students soon learned that the high standards which he expected of them were a reflection of his own approach to the practice of surgery. Technically also he was a fine craftsman, and while not normally a fast operator he could act swiftly when the occasion demanded. Although a trained neurosurgeon, he soon showed that he was a master of all branches of the craft of surgery, and when in Aberdeen he was looked upon as a skilled abdominal and urological surgeon. At that time the chair was not a full-time one, and, in addition to his teach-

ing and the establishment of a department of surgery which produced much original work, he had a considerable private practice, and many general practitioners and patients were grateful for his surgical help. Personally his years in Aberdeen for him and his family were happy ones. In the difficult years in Edinburgh during and after the second world war he was at times heard to say that he had his application all ready if the opportunity to return to Aberdeen should arise.

During the war years he worked extremely hard. He succeeded to the chair of systematic surgery in Edinburgh just as war was declared. In spite of all the difficulties of wartime, he maintained the high standard and the volume of work from the department which had been established by Sir David Wilkie, and made it a Mecca for the many Commonwealth and American surgeons whom the war brought to this country. He carried on the clinical, administrative, and teaching duties of the chair with a depleted staff. If this was not enough for one man, he was also surgical director for South-east Scotland, ran the unit for peripheral nerve and blood vessel injuries at Gogarburn Hospital, and for a time also was in charge of a surgical unit at the Western General Hospital. In addition to these activities in Edinburgh he served on the Medical Research Council and on several of its committees, and was also a member of the Goodenough Committee on medical education. These commitments meant many weary nights in blacked-out trains held up by air raids.

When peace came he seemed to be busier than ever. In 1946 he took on the additional duties of the chair of clinical surgery, and for a further ten years he led the life of a busy surgeon, teacher, and administrator. He also travelled extensively, being in great demand as a lecturer and medical ambassador. These were difficult years, and it came as no surprise to those who knew him well that he decided the pace was too fast and that he should retire from both chairs. In his retirement it was a source of great pleasure to him that his Alma Mater, which had been unable to find a suitable place for him in his youth, should make amends by electing him an assessor on the University Court, and in recent years Glasgow University has benefited greatly from his wise counsel.

TERENCE EAST, M.A., D.M., F.R.C.P.

T. K. L. writes: In the various accounts that have been written about this scholar-physician (obituary, 9 September, p. 684) I do not think sufficient emphasis has been put on the fact that not only was he a remarkably able teacher but he thoroughly enjoyed teaching. Admittedly it was necessary to listen carefully to his remarks, because he always spoke quietly and rarely repeated himself, but to attend his ward rounds was of great educational value and an unforgettable pleasure. By careful analysis and an assessment of the merits of every symptom and physical sign he had a remarkable facility for making the most difficult clinical problem appear perfectly simple. I consider that to have served as one of his house-physicians was the greatest privilege, for at that stage one appreciated his teaching all the more and, in addition, one found that in Terence East one had a staunch friend and a sound adviser.

News and Notes

EPIDEMIOLOGY

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of whooping-cough and acute pneumonia in England and Wales.

Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.

Infectious Diseases

Areas where numbers of notifications were high in the latest two weeks for which figures are available.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 23 September (No. 38) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included). Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

MOTORING

Progress Towards Safer Night Driving

[FROM OUR MOTORING CORRESPONDENT]

Autumn is traditionally the time of year for criticism and reappraisal of car headlamp systems and the ways in which they are used (and misused). The exercise is of more than ordinary interest on this present occasion for two reasons—the new ideas which are to be found in some of the 1968 models and the probable intention of the Ministry of Transport to take a decision, before long, on the vexed question of the extent to which headlamps should be used when driving in cities and their suburbs.

It is a sad commentary on the way in which we deal with traffic problems that there is still no legal obligation to fit headlamps to cars used in the United Kingdom, though if they are fitted certain specific conditions must be met. Consequently no legal ruling about the use of headlamps by drivers can be given until the fitting of headlamps is itself made obligatory. This first step is now said to be "imminent."

For several winters past the City of Birmingham has sponsored a full-scale experiment in which large numbers of drivers have voluntarily used dipped headlamps continuously at night, no matter what the level of street lighting might be in any particular area. Accident statistics appear to show that greater safety has resulted as compared with the more general practice (in the U.K.) of using sidelamps alone in built-up areas. The driving public does not seem to have been particularly bothered by glare from either approaching or following cars, which suggests that more than ordinary care was taken to have the lamps properly adjusted.

We are so insular in these matters that little notice is taken of the fact that the use of headlamps has always been obligatory, whenever a car is on the move at night, in large areas of the United States and in Europe. I have myself had much driving experience under these conditions in large American cities and can vouch for the fact that, apart from giving better driving vision, dipped headlamps identify an approaching car more positively than sidelights, the use of the latter being confined to parked cars. It is interesting to recall that over a year ago British automobile engineers (through the Society of Motor Manufacturers and Traders) pronounced themselves in favour of the obligatory use of headlamps on all moving vehicles at night.

Dim-dip Lamps

The Road Research Laboratory has strongly advocated an alternative scheme as being more likely to find ready acceptance from British drivers, many of whom show an extraordinary disinclination to use their headlamps—or even their sidelamps for that matter. The R.R.L. plan involves complicating the electrical system to provide a "dim-dip" stage. No extra switch position is needed because (provided the sidelamps are switched on), the dimmed and dipped head-

lamps light up automatically with the use of the ignition switch and consequently remain in action whenever the car is on the move. The usual switches provide for the alternative use of fully illuminated headlamps, both dipped and undipped.

In my view a serious disadvantage of this plan (which has been tried experimentally on a number of London taxis) is that the driver has a discretionary option on whether to use "dim-dip" or "normal-dip" headlamps. He can therefore deprive himself of a safe driving light in a badly lit suburban street by forgetfully (or deliberately) leaving the lamps in the dim-dip condition. We should be moving towards fewer alternatives and simpler driving conditions rather than adding to our difficulties. However, the R.R.L. has taken a firm stand versus the motor industry (and the City of Birmingham), and the decision now rests with the Ministry of Transport.

To make the general use of dipped headlamps tolerable it is certainly essential that car-lighting systems should be serviced more frequently and more efficiently than at present. Comparatively few garages can give an immediate check of headlamp alignment using quick and accurate equipment. Every time the R.A.C. (or some similar body) offers special local testing facilities on a "free trial" basis a high proportion of the cars tested are found to have maladjusted lamps.

The adjustment is fairly critical and should be done with the car loaded to represent normal conditions of use. It is a serious disadvantage of the softer and more comfortable suspension systems now in vogue (even in smallish cars) that the addition of rear-seat passengers or luggage can tilt the vehicle sufficiently to dazzle oncoming drivers even though the beams are dipped. For example, if the additional load depresses the rear springs by an extra inch (2.5 cm.), leaving the front springs unaffected, the fore-and-aft trim of a typical medium-sized car will alter to an extent sufficient to lift the beam by about 12 in. (30 cm.) at a distance of 100 ft. (30 m.).

There are two ways of overcoming the difficulty. The first requires the use of an elaborate self-levelling suspension system which automatically compensates for changes of load. This is so far found only on a few relatively costly cars (such as the Rolls-Royce and some Mercedes models) but will probably become more widely used in the future. The second plan is to link the headlamps to the suspension system in such a way that their alignment relative to the road is preserved when the load changes or even when the car pitches on an undulating surface. This latter method is used in the 1968 version of the D-type Citroën Pallas model.

Pattern of Beam

The distribution of light—or pattern of the beam—depends on the spatial relation-

ship between the filament and the reflector in addition to the precise shape given to the latter part of the lamp. Consequently it is most important that reflectors and bulbs should be made and assembled with a high degree of accuracy. A bold solution to this problem is represented by the "sealed beam" unit in which a glass envelope forms both a reflecting surface and a vacuum container for the filament (Fig.). There is no separate bulb, so that the relative positions of the filament and the reflecting surface can be

A Lucas "sealed beam" headlamp in section, showing how the filament is fixed within the glass container.

closely controlled in manufacture and will remain unaltered in use. The reflecting surface is also well protected from deterioration. Unfortunately, the sealed-beam principle has not yet been applied to the rectangular type of headlamp which has latterly become a popular competitor to the circular lamp.

Four-headlamp systems have the advantage that one pair can be expressly designed to provide dipped beams and the other pair to provide driving beams. This leads to greater functional efficiency and consistency in manufacture than with normal dual-purpose lamps which use bulbs with two filaments. In the new Citroën system already mentioned the inner pair of long-range driving lamps are of the powerful quartz-iodine type and are coupled to the steering so as to turn with the vehicle. It is the outer pair of dipped lights which are self-levelling in relation to springing movements.

Earlier attempts to use steerable and self-levelling devices were unsuccessful because they did not continue to work with sufficient precision after normal wear and tear on the road. It will be interesting to see whether the resourceful Citroën engineers have surmounted this difficulty, but so far no details of the design have been released. On some American cars "seeing round corners" at night is made possible by providing two additional fixed lamps, set obliquely. These

light up automatically as a supplement to the headlamps when the steering is moved away from the straight-ahead position.

The pop-up headlamp, becoming popular for streamlined sports cars, has the slender

advantages of keeping clean when not in use and contributing to a sleek, streamlined appearance. One hopes that the mechanism is fully reliable, because under present driving conditions the transition from sidelamps to

headlamps is often an urgently important matter. If headlamps must be concealed, it seems a better plan to cover them with hinged doors, or sections of grille, so that the lamp itself remains fixed.

MEDICAL NEWS

Bicentenary of Leeds General Infirmary

On 2 October the Leeds General Infirmary celebrated the bicentenary of its foundation. The first annual report recorded that 89 in-patients and 272 outpatients were treated in the first year at a cost of £469. In 1966, more than 20,000 inpatients and nearly 700,000 outpatients were treated. The foundation stone of the present infirmary was laid in 1864, the building being completed in 1868. Now, 100 years later, a new teaching hospital and medical centre is to be built on the site of the infirmary and its satellite hospitals. With a total of 1,400 beds the new infirmary will be one of the largest hospitals in Europe. Among the events marking the bicentenary was a commemorative service in Leeds Parish Church and the opening of a new eye ward and theatre by Sir DONALD KABERRY, M.P., chairman of the board of governors.

Postgraduate Medical Education

The Central Committee on Postgraduate Medical Education (Great Britain) met on 29 September, when there was a discussion between the committee and representatives of the Ministry of Health and the Scottish Home and Health Department on the staffing structure in the hospital service in relation to service and to education and training.

Early Detection of Disease

A project to ascertain the benefits of early diagnosis and treatment of disease is being organized by the department of social medicine at St. Thomas's Hospital Medical School in collaboration with the South-east Metropolitan Regional Hospital Board and the health department of the London Borough of Bromley. It is sponsored by the Ministry of Health. Announcing the project, the Ministry says it will be carried out in a group general practice with a list of about 12,000. Initially, persons between the ages of 40 and 64 will be examined. They will be invited to undergo a series of tests and to answer a simple questionnaire. After the examination they will see their own doctor, who will have the results of the tests before him. By comparing the experience of tested and untested groups an assessment will be made of how much the medical services are used by each group and how much benefit can be derived from early diagnosis and treatment. Another aim of the project is to study ways in which the general practitioner can be given help to relieve him, as far as possible, of work other than clinical work.

Smoking Habits of Medical Students

Attitudes to smoking among medical students are not greatly influenced by their training, according to the findings of a survey conducted by the Government Social Survey for the Ministry of Health. The smoking habits of medical and non-medical students

were found to be similar, except that the incidence of smoking was lower among female medical students than among the others, and that pipe-smoking was more popular among medical students. Attempts to stop smoking, or to cut it down, were most frequent during the first year of clinical training. At this stage the proportion of smokers who thought that doctors should set an example to their patients and to the public rose to a peak. Thereafter the reaction against smoking declined. Only about half of the third-year clinical students thought that doctors should advise their patients not to smoke. The report concludes that if the antismoking campaign is to succeed more needs to be done in medical schools to discourage students from smoking. (*Medical Students' Attitudes Towards Smoking*, H.M.S.O., 25s.)

Mining Deaths Lowest Recorded

Last year 160 people were killed in mining accidents and 1,061 seriously injured. This represented an overall reduction of 11.2% on the figures for 1965. There was, however, a reduction of about 7% in the number of man-shifts worked. The accident rate—that is, the number of accidents per 100,000 man-shifts—fell from 1.31 to 1.26. Over the past four years it has fallen by about 12%. For the first time the number of men killed in haulage and transport accidents (67) exceeded those from falls of ground (60). In his report (H.M.S.O., 6s.) the Chief Inspector of Mines and Quarries notes that the number of new cases of pneumoconiosis diagnosed by the Pneumoconiosis Medical Boards has fallen considerably in recent years. "The comparison of the results obtained in 1966 [937 cases] with those five years earlier [2,768 cases] indicates that there is every reason to hope that dust suppression measures are beginning to have their effect."

Progress in Smoke Control

Premises in smoke control areas in Great Britain now number more than 3 million. The Greater London region continues to lead, with over 61% of its premises covered by orders. Next come Yorkshire and Humberside (35%) and the North-West (34%). A table in the new year book of the National Council for Clean Air, which gives these figures, shows that domestic fires were responsible for the emission of 900,000 tons of the 1,100,000 tons of smoke that polluted the atmosphere in 1965.

Chelmsford Medical Society

At the annual general meeting of the Chelmsford Medical Society the following officers were elected: *president*, Dr. K. A. D. TURK; *treasurer*, Dr. K. R. ABERDOUR; *secretaries*, Dr. K. H. NICKOL and Mr. G. L. S. RANKIN.

People in the News

► Professor K. W. DONALD has been appointed a physician to the Queen in Scotland in place of Professor Sir EDWARD J. WAYNE, who has resigned.

► Professor MARTIN ROTH has been elected to the Mayne Guest Professorship in the University of Queensland, Australia. He will be attached to the department of psychological medicine and will take up his duties at the end of March 1968.

► Major-General J. A. D. JOHNSTON has been appointed honorary physician to the Queen.

► Colonel CAMERON WEYMES has been appointed honorary surgeon to the Queen.

► Professor A. L. D'ABREU has been appointed a deputy lieutenant for the County of Warwick.

► Sir JOHN ECCLES, F.R.S., is to join the faculty of health sciences at the State University of New York at Buffalo in July 1968.

News in Brief

PRINCESS ALEXANDRA has agreed to become the patron of the National Kidney Research Fund.

The Medical Research Council has set up a powered limbs research unit at West Hendon Hospital, London, under the direction of Dr. A. B. KINNIER WILSON.

Grants and Awards

Dr. WINIFRED M. WATKINS, Ph.D., and Professor W. T. J. MORGAN, F.R.S., of the Lister Institute of Preventive Medicine, London, will share the 1967 Karl Landsteiner memorial award of the American Association of Blood Banks.

Among the recipients of the third annual Barraquer Award is Mr. PETER CHOYCE, F.R.C.S.

Recent Publications

Scottish Health Service Studies: *Cancer Registration, 1959-61*, issued by the Scottish Home and Health Department. A review of the organization of cancer registration in Scotland is being undertaken.

The Mental Hospital Library, by Mr. D. Boorer, R.M.N., deputy editor of the *British Hospital Journal and Social Service Review*, is based on nearly two years' experience of working as librarian at Moorhaven Hospital, Ivybridge, Devon. The pamphlet is published by the Library Association, 7 Ridgmount Street, Store Street, London W.C.1, price 10s. (7s. 6d. to members of the Library Association).

Coming Events

Cambridge University School of Clinical Research and Postgraduate Medical Teaching.—Postgraduate courses for general practitioners, 1 October 1967 to 31 July 1968. Details from Secretary, Cambridge University Medical School, Tennis Court Road, Cambridge.

Oxford Seminar on Designing for the Disabled.—20 October, College of Technology, Oxford. Details from Mr. J. R. REGAN, Assistant Regional Architect of the Oxford Regional Hospital Board (Oxford 64861).

Ipswich Postgraduate Medical Centre.—Official opening by Sir GEORGE PICKERING at the Ipswich and East Suffolk Hospital, Anglesea Road Wing, 24 October, 2.15 p.m.

Medical Society for the Study of Venereal Diseases.—Meeting, "Recruitment to the Speciality of Venereology," 27 October, 7 p.m. for 7.30 p.m., 11 Chandos Street, London W.1.

Association of Clinical Biochemists: Southern Region.—Symposium, "Chemical Pathology in Relation to Neuropathology," 28 October, 10 a.m., National Hospital, Queen Square, London W.C.1. Details from Dr. V. MARKS, Area Laboratory, West Park Hospital, Epsom, Surrey.

Medical Practitioners Union.—Medical World conference, "The Future of the National Health Service," 29 October, 10 a.m. to 4.30 p.m., Queen Mary College, Mile End Road, London E.1. The chairman will be Sir MAX ROSENHEIM. Admission is free, but tickets for luncheon (16s.) must be obtained from the Conference Secretary, M.P.U., 55-56 Russell Square, London W.C.1.

Peripheral Circulation Group.—Symposium, "Peripheral Circulatory Assessment in Human Arterial Disease," 31 October, 8 p.m., Royal Infirmary, Glasgow.

Institution of Mechanical Engineers.—Symposium on basic problems of artificial prehension, movement, and control of artificial limbs, 31 October to 1 November 1968. Details from Mr. E. P. DAVIES, Groups Department, Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, London S.W.1.

Queen's Institute of District Nursing: Welsh Federation.—Conference, "Care and Rehabilitation of the Elderly," 1-2 November, Sherman Conference Hall, Ty Maeth, King George V, Drive East, Cardiff. Fee £1 15s. Details from General Secretary, Q.I.D.N., 57 Lower Belgrave Street, London S.W.1.

King Edward's Hospital Fund for London.—Conference, "Damage in Hospitals," 2 November, Hospital Centre, 24 Nutford Place, London W.1. Details from the Hospital Centre.

Share-Jones Lecture in Veterinary Anatomy.—"Adventures in Neuroendocrinology," by Professor B. A. CROSS, 2 November, 6.30 p.m., Royal Veterinary College, Royal College Street, Camden Town, London N.W.1. Those wishing to attend should notify the secretary of the college.

Institute of Ophthalmology.—Open day 2 November. Admission by ticket, obtainable from the Secretary, Institute of Ophthalmology, Judd Street, London W.C.1.

Glasgow Postgraduate Medical Board.—Conference, "Ischaemic Heart Disease," 9-10 November, Royal College of Physicians and Surgeons of Glasgow. For details see advertisement on p. xxxix.

Society for Psychosomatic Research.—Conference, "Disorders of Sex and Reproduction—Psychosomatic Aspects," 10-11 November, Royal College of Physicians,

London. Details from Conference Secretary, Dr. C. J. LUCAS, 17 Gordon Street, London W.C.1.

Society for Medical and Dental Hypnosis: Midlands Branch.—Intermediate course in "Techniques and Applications of Hypnosis," 11-12 November, Grand Hotel, Colemore Row, Birmingham. The course registration fee is £10 10s. and applications should be made to Mrs. S. NEWBERRY, 1 White House Green, Solihull, Warwicks.

Royal Northern Hospital.—Symposium on clinical immunology for general practitioners, 16-17 November, Royal Northern Hospital, London N.7.

London University.—Course of four Heath Clark lectures, "Perspectives in Health Planning," by Dr. A. ENGEL (Sweden), 14, 16, 20, and 21 November, 5.30 p.m., London School of Hygiene and Tropical Medicine, Keppel Street, London W.C.1. Admission free, without ticket.

Queen's Institute of District Nursing: Home Counties Federation.—Conference, "The Changing Scene in Domiciliary Nursing," 17 November, Assembly Hall, Royal Commonwealth Society, Northumberland Avenue, London W.C.2. Fee £1 12s. 6d. (including refreshments). Details from General Secretary, Q.I.D.N., 57 Lower Belgrave Street, London S.W.1.

Institute of Child Health.—Seventh course on "Problems of Developmental Neurophysiology and E.E.G. in Paediatrics," 16, 17, 18 November, Hospital for Sick Children, Great Ormond Street, London W.C. Details from the Dean, Institute of Child Health, 30 Guilford Street, London W.C.1.

Sussex Postgraduate Medical Centre.—Symposium on chronic renal disease, 18 November. For programme and admission ticket apply to Secretary of Centre, Brighton General Hospital, Elm Grove, Brighton 7.

Royal College of General Practitioners.—James Mackenzie lecture by Dr. RONALD GIBSON, "Lucerna Pedibus Meis," 18 November, 11 a.m., followed at 2 p.m. by annual general meeting, B.M.A. House, London W.C.1. Annual symposium, "Combined Operations—Medicine, Science, and Humanism," 19 November, 9.15 a.m., Wellcome Building, Euston Road, London N.W.1.

University of the West Indies.—Fourth annual workshop in otolaryngology, 14-20 January 1968. Applications to Dr. K. A. MCNEILL, University of West Indies, Kingston, Jamaica.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 16 October

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.
HUNTERIAN SOCIETY.—At Talbot Restaurant, London Wall, 7 p.m., presidential address by Dr. C. C. Chesterman: Tropical Trail.
INSTITUTE OF DISEASES OF THE CHEST.—6.15 p.m., Dr. J. W. Pierce: The Oesophagus.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., combined staff consultation clinical meeting.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 11.15 a.m., discussion: Contracted Pelvis. Speakers, Mr. J. M. Brudenell, Mr. J. M. Holmes.●

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr. J. M. Talbot: Pathology of Trauma—Wound Infection; 6.30 p.m., Dr. G. B. Hill: Design of Clinical Trials.●
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Dr. O. H. Belam: Some Hazards of Surgery and Anaesthesia in Patients under Treatment with Modern Drugs. (2) 6.30 p.m., Mr. R. B. Zachary: Obstructive Lesions of the Alimentary Tract in the Newborn.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. M. Turner-Warwick: Rheumatoid Factors and Lung Disease.

Tuesday, 17 October

DOLTON AND DISTRICT MEDICAL SOCIETY.—At Gymnasium, Bolton Royal Infirmary, 8.15 p.m., clinical meeting.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Beveridge Hall, Senate House, London University, 5.30 p.m., Lord Florey, O.M., F.R.S.: Elements of the Vascular System.
CAMBRIDGE MEDICAL SOCIETY.—At Blue Room, Dorothy Restaurant, 8.30 p.m., jointly with University Medical Society, debate by Dr. M. H. Pappworth (for) and Professor I. H. Mills (against): This House Believes that Experimentation in Patients has Reached an Unacceptable Level.
HORDER MEMORIAL TRUST.—At Physiology Lecture Theatre, St. Bartholomew's Hospital Medical College, 5 p.m., Horder memorial lecture by Professor D. A. K. Black: Chronic Renal Failure.
NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., Dr. R. Isaac: The Happy Puppet Syndrome (case and film).
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Mr. H. Shaw: Diagnosis and Management of Tumours of the Larynx and Pharynx. (2) 6.30 p.m., Dr. Deborah Doniach: Auto-immune Disorders in relation to Surgery.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Mr. A. G. Cox: Surgery in Peptic Ulcer.
WHIPPS CROSS HOSPITAL.—At Medical Education Centre, 1 p.m., clinical meeting.

Wednesday, 18 October

B.B.C. 1 TELEVISION.—11.15 p.m. (approx.), medicine today: Rheumatoid Arthritis. (Sponsored by A.S.M.E.)
CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. L. Szur: Principles of Dermatological Radiotherapy—I.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. Lloyd Rusby: Extrapulmonary Manifestations of Carcinoma of the Bronchus.
INSTITUTE OF UROLOGY.—5 p.m., Mr. J. P. Williams: Surgery of the Ureter.
KENNEDY INSTITUTE OF RHEUMATOLOGY.—At rear of West London Hospital, 5 p.m., Dr. J. Hobbs: Immunoglobulins.
MANCHESTER MEDICAL SOCIETY: Section of Paediatrics.—At Large Anatomy Theatre, Manchester University Medical School, 5 p.m., Dr. M. C. Joseph: The Facies in Down's Syndrome—A Study by Measurement.
OXFORD UNIVERSITY MEDICAL SCHOOL.—At Nuffield Maternity Home Lecture Theatre, Radcliffe Infirmary, 5 p.m., Dr. J. Last: Career Aspirations and Training of Young British Doctors.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Professor R. Barnes: Injuries of the Cervical Spine. (2) 6.30 p.m., Mr. V. Logue: Neurosurgical Relief of Pain.
ROYAL FREE HOSPITAL.—5.15 p.m., Dr. I. Chanarin: Vitamin B₁₂ and Folate Metabolism in Man.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conferences by Dr. G. Neale: Steatorrhoea; Dr. D. J. Evans: Liver Failure. (2) 2 p.m., Dr. T. R. E. Pilkington: Ketosis.
STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. Margaret Walshe: Awful Warnings. (2) 6 p.m., Dr. B. G. Dooley: Industrial Poisons.
WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Professor A. W. Woodruff: Some Problems Concerning Tropical Disease in Britain.
WHIPPS CROSS HOSPITAL.—At Medical Education Centre, (1) course for general practitioners, 2 p.m., Mr. J. S. Conway: Causes of Blindness; 3 p.m., Dr. A. A. G. Lewis: Recent Developments in the Diagnosis and Management of Diabetes. (2) 8.30 p.m., Dr. R. M. Mason: Gout and Pseudo-gout.
WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—At Staff Recreation Hall, 8.30 p.m., clinical quiz by Dr. D. Geraint James.

Thursday, 19 October

ABERDEEN UNIVERSITY FACULTY OF MEDICINE.—At Large Lecture Theatre, University Medical Buildings, Foresterhill, 5 p.m., Dr. J. Williamson: Old Age—a Positive Approach.
ADDENBROOKE'S HOSPITAL.—At M.R.C. Lecture Theatre, New Addenbrooke's Hospital, 8.30 p.m., Dr. J. V. Farman: Circulatory Effects of Atropine and Gallamine.
BRITISH INSTITUTE OF RADIOLOGY.—6 p.m., discussion group; 8 p.m., presidential address by Dr. R. D. Hoare.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Professor E. Jean Hanson, F.R.S.: Molecular Structure of Muscles in Relation to Mechanism of Contraction.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—Queen Charlotte's Hospital, 2 p.m., Professor J. K. Russell: Diagnosis of Placenta Praevia.

LEEDS UNIVERSITY FACULTY OF MEDICINE.—At Rupert Beckett Lecture Theatre, the University, 3.15 p.m., inaugural lecture by Sir Geoffrey Vickers, V.C.: What to Expect of a Doctor.

MANCHESTER MEDICAL SOCIETY.—At Large Anatomy Theatre, Manchester University Medical School, 4.30 p.m., presidential address by Mr. D. S. Poole Wilson: Urology—the Past, the Present, and the Future.

MANCHESTER MEDICAL SOCIETY: SECTION OF ANAESTHETICS.—At Theatre B, Roscoe Building, Brunswick Street, 8 p.m., presidential address by Dr. J. Raventos: Anaesthetics and Research.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Mr. D. S. M. Barlow: Management of Chest Injuries. (2) 6.30 p.m., Mr. J. Tulloch Brown: Fractures of the Upper End of the Femur.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Mr. W. H. Stephenson: Post-irradiation Fractures.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., presidential address by Professor P. C. C. Garnham, F.R.S.: Reflections on Laveran, Marchiafava, Golgi, Koch, and Danilewsky after 60 years.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Mr. F. E. Loeffler: Induction of Ovulation.

Friday, 20 October

BIOLOGICAL ENGINEERING SOCIETY.—At Botany Theatre, University College, Gower Street, London W.C.1, 6 p.m., Woolmer memorial lecture by Professor A. R. Huxley, F.R.S.: Forgetting and Rediscovery in Physiology.

BRITISH INSTITUTE OF RADIOLOGY.—2 p.m., radiobiology meeting.

INSTITUTE OF CHILD HEALTH.—At Kennedy Lecture Theatre, 5.30 p.m., Professor J. Tizard: Problems of Education of Handicapped Children.

KENT POSTGRADUATE MEDICAL CENTRE AT CANTERBURY.—At Kent and Canterbury Hospital, 8.30 p.m., Dr. P. J. Lawther: Air Pollution and Health.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—8.15 p.m., Dr. L. C. Payne: Automation in Medicine.

LONDON SOCIETY OF FAMILY PLANNING DOCTORS.—At West Hall, Royal Society of Medicine, 8.15 p.m., Mr. P. L. C. Digory: Complications of I.U.D.s.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—(1) 5.15 p.m., Mr. L. Kessel: Management of Fractures and Dislocations in the region of the Shoulder Joint. (2) 6.30 p.m., Mr. S. R. Mawson: Management of Infections of the Mastoid Process.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 10.15 a.m., Dr. J. A. Dossett: A Simplified Nomenclature of Breast Disease. (2) 11.30 a.m., Mr. J. I.

Burn: clinicopathological conference (Breasts). (3) 4 p.m., Dr. Wilfrid Oakley: Some Complications of Diabetes and their Treatment.

Saturday, 21 October

ABORTION LAW REFORM ASSOCIATION.—At Kensington Central Public Library, Phillimore Walk, 7 p.m., annual public meeting: Abortion Bill—Will it Work?

Appointments

BIRMINGHAM REGIONAL HOSPITAL BOARD.—J. W. H. Foy, M.R.C.S., D.M.R.E. (whole-time consultant radiologist to the St. George's and Stafford groups); I. S. Chatha, M.B., F.R.C.S., D.O. (part-time consultant ophthalmologist to the Wolverhampton and Lichfield, Sutton Coldfield, and Tamworth groups); W. M. Park, M.B., D.M.R.D. (whole-time consultant radiologist to the Shrewsbury group and the Robert Jones and Agnes Hunt Orthopaedic Hospital).

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—R. D. Jones, M.B., M.R.C.P.Ed., D.C.H. (consultant in paediatrics, Norfolk and Norwich area); R. G. Gibbs, M.B., M.R.C.P. (consultant physician, Norwich, Lowestoft, and Great Yarmouth Hospital group).

MANCHESTER REGIONAL HOSPITAL BOARD.—J. S. S. Stewart, M.B., F.R.C.S. (whole-time or maximum part-time consultant surgeon, Wigan and Leigh group of hospitals); D. H. G. Cowie, M.B., M.R.C.O.G. (whole-time or maximum part-time consultant obstetrician and gynaecologist, West Manchester group of hospitals); K. J. Rees, M.B., M.R.C.O.G. (whole-time or maximum part-time consultant obstetrician and gynaecologist, Stockport and Buxton group of hospitals); Edith M. Varley, B.M., F.F.A.R.C.S. (whole-time or maximum part-time consultant anaesthetist, South Manchester group of hospitals).

MINISTRY OF DEFENCE.—R. A. Kemp Harper, M.D., F.R.C.P., F.F.R. (consulting radiologist to the Royal Navy).

MINISTRY OF OVERSEAS DEVELOPMENT.—Catherine A. Ryan, M.B., F.F.A.R.C.S., D.A. (anaesthetist with the British Paediatric Unit of the Children's Hospital in Saigon).

NEWCASTLE REGIONAL HOSPITAL BOARD.—J. G. Crumney, F.R.C.S. (consultant in orthopaedic surgery, West Cumberland); C. H. McCulloch, M.B., F.F.A.R.C.S. (consultant in anaesthetics, Gateshead); F. Clark, M.B., M.R.C.P. (consultant in general medicine, Newcastle); D. Smith, M.B., M.C.Path. (consultant in pathology, West Cumberland); R. G. Gold, M.B., M.R.C.P., M.R.A.C.P. (consultant in cardiology, Newcastle); E. Holmes, M.B., D.A. (consultant in anaesthetics, Sunderland); F. Fleming, M.B., F.R.C.S., D.L.O. (consultant in otolaryngology, South Tyneside); J. C. Linn, M.B., D.M.R.D. (consultant in radiology, Sunderland).

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—J. Q. Mathias, M.D., M.R.C.P. (part-time

consultant physician in general medicine to Tottenham group of hospitals).

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—P. M. Jackson, M.B., D.P.M. (consultant psychiatrist, Devon and Exeter clinical area (Royal Western Counties)); D. E. P. Jones, B.M., F.R.C.S., D.O. (consultant ophthalmologist, Bath clinical area); N. Seymour, M.B., F.R.C.S. (consultant orthopaedic surgeon, Plymouth clinical area); P. D. Mulcahy, M.D., M.R.C.P. (consultant physician, Plymouth clinical area); N. M. C. Mayne, M.D., M.R.C.P. (consultant general physician, North Gloucestershire clinical area).

Universities and Colleges

LONDON

M.D.—E. H. Burgess, Lorna I. M. MacLay.
M.S.—O. H. Shaheen, M.R. H. Ashken.
M.Phil.—In the Faculty of Medicine: Margaret D. Walker.
Ph.D.—In the Faculty of Medicine: R. J. Anderson, D. K. Brooks, M. N. Cauchi, G. G. S. Collins, J. W. Freston, Francesco B. Giannelli, S. A. H. Khalil.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

Appointment.—L. J. Bruce Chwatt, M.D., M.P.H., D.T.M.&H. (senior lecturer (technical assistance) in the Ross Institute of Tropical Hygiene).

BIRMINGHAM

Appointments.—Dr. A. S. Abraham (research fellow in the Department of Medicine); Dr. R. A. Thompson (temporary lecturer in the Department of Experimental Pathology), Dr. M. J. McCulloch (lecturer in child psychiatry, Department of Psychiatry).

LIVERPOOL

Appointments.—Dr. R. F. Roos (lecturer in obstetrics); Dr. J. T. Quinn and Dr. J. Price (lecturers in psychiatry).

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS OF GLASGOW

On 29 September the following were admitted Fellows *qua* Surgeon: A. F. A. Fattah, T. Bhaduri, J. Dudgeon, J. N. Gangopadhyay, E. S. Glen, S. E. P. Miller, J. C. Mustardé; Members *qua* Physician: A. H. Barlas, W. B. Doig, T. Fyfe, M. A. Halim, M. H. Husain, A. F. M. A. Islam, Ida J. McFadyen, T. Myint, R. L. Willing.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the College held on 30 September the following lecturers were appointed for 1967: Dr. R. W. Barter (Green-Armytage Anglo-American lecture); Mr. F. E. Stabler (William Meredith Fletcher Shaw lecture); Dr. W. G. Cosbie (J. Y. Simpson Orator).

The following were admitted to the Membership *in absentia*:

I. A. W. Hamdy, F. S. Lynes, R. G. Selvanayagam.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitology*, London W.C.1. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

BRITISH JOURNAL OF INDUSTRIAL MEDICINE

Contents of the October issue are as follows:

Assessing the Heat Stress and Establishing the Limits for Work in a Hot Mine. C. H. Wyndham, A. McD. Allan, G. A. G. Bredell, and R. Andrew.

Treatment of Lead Poisoning: A Comparison Between the Effects of Sodium Calciumedetate and Penicillamine Administered Orally and Intravenously. Stig Selander.

Control of Lead Workers by Determination of Urinary δ -Aminolaevulinic Acid. Kim Cramér and Stig Selander.

A Dry Ashing Method for the Determination of Blood Lead Using Cathode Ray Polarography: Comparison with a Wet Ashing Technique. A. A. Cernik.

A Simplified Procedure for the Determination of Urinary δ -Aminolaevulinic Acid. M. K. Williams and J. D. Few.

Auditory and Subjective Effects of Airborne Noise from Industrial Ultrasonic Sources. W. I. Acton and M. B. Carson.

Incorporation of Uranium. I. Distribution of Intravenously and Intraperitoneally Injected Uranium. G. Walinder, L. Hammarström, and U. Billadelle.

Incorporation of Uranium. II. Distribution of Uranium Absorbed Through the Lungs and the Skin. G. Walinder, B. Fries, and U. Billadelle.

Metabolism of Ethylene Glycol Dinitrate and its Influence on the Blood Pressure of the Rat. D. G. Clark and M. H. Litchfield.

Tryptophan Content of the Serum Albumin of Normal and of Cadmium-poisoned Monkeys. J. E. Kench and Elizabeth M. Sutherland.

A Study of the Skin Absorption of Ethylbenzene in Man. Tadeusz Dutkiewicz and Halina Tyras.

Miscellanea:

Lead Poisoning in Jewellery Enamellers. R. Fothergill, M. D. Kipling, and A. B. Weber.

Book Reviews. Index.

Volume 24, No. 4. Yearly subscription (4 numbers) £3 3s., abroad £3 10s.

ABSTRACTS OF WORLD MEDICINE

The October issue (Volume 41, No. 10) is now available. Published monthly. Yearly subscription £6 6s. U.S.A. \$18. Single number 12s. 6d.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY 21 OCTOBER 1967

Pointers

Hazards of Therapy: Carcinogenic action of new therapeutic agents cannot be predicted from their chemical structure, and co-operation between laboratory workers and clinicians is of paramount importance in avoiding this potential danger (p. 129).

Acrylamide Poisoning: Six cases in Britain. Clinically characterized by peripheral neuropathy and a midbrain disturbance. Prevention is relatively easy (p. 134). Leader at p. 125.

Fructose Intolerance: Genetically determined metabolic disorder which may present in infancy, childhood, or adult life. It is prevented by excluding fructose from the diet (p. 138).

Pulmonary Valve Closure: Delay, causing splitting of second heart sound, observed in eight patients with renal failure. Splitting disappeared after correction of oedema. It seems a useful sign of fluid overload (p. 141).

Role of Glucagon: Blood glucose levels affected more by its glycogenolytic action than by its insulin release action (p. 145).

Coronary Occlusion and the Thyroid: Blood fibrinolytic enzyme system is probably influenced by thyroid hormones (p. 147).

Fat Embolism: Lipaemia found in series of patients followed after trauma, one-third of whom had fat embolism. Use of clofibrate in a second series reduced lipaemia, suggesting that the cause of embolism may be metabolic rather than traumatic (p. 149).

Behçet's Syndrome: Occurrence of aortic aneurysms emphasizes the general nature of this syndrome (p. 152).

Case Reports: Hepatic murmurs and anaemia (p. 154). Jaundice after carbamazepine (p. 155). Myelomatosis diagnosed by electrophoresis of C.S.F. (p. 156).

Spare-part Surgery: Recent advances in the use of inert, dead, or living foreign materials to replace or repair diseased or missing organs (p. 157).

Paediatric Neurology: Management of children with progressive neurological handicap (p. 162).

L.S.D.: Risk of foetal abnormality (p. 124).

Gastritis: Description of the two distinct and probably unrelated types and their clinical significance (p. 164).

Scottish Council: Meeting (*Supplement*, p. 17).

"Better Medical Care": Edinburgh Conference (*Supplement*, p. 18).

Overseas Affairs: Service overseas discussed (*Supplement*, p. 20).

Consultant Merit Awards: Results of ballot (*Supplement*, p. 22). Leader at p. 128.

Medical Management Services: B.M.A. Council's resolutions (*Supplement*, p. 23).

Teaching the Behavioural Sciences

One of the most persistent criticisms of the medical curriculum has been that it paid too little attention to the teaching of psychiatry and of the psychological aspects of health and disease. As late as 1960 an international survey submitted to the World Health Organization could state that "in the United Kingdom and British Commonwealth psychiatric teaching in general is still hardly a legitimate part of the medical curriculum, in spite of the repeated requests for improvement, which have come from both faculty and undergraduates."¹

There has been no lack of proposals how to incorporate into medical education the great advances in the study of normal and abnormal behaviour as well as in the treatment of mental disorders. The memoranda submitted to the General Medical Council by the Royal Medico-Psychological Association² in 1965 and the British Medical Association³ in 1966 both emphasized the need for the teaching of behavioural sciences in the preclinical curriculum side by side with anatomy and physiology. A W.H.O. Expert Committee had made similar recommendations in 1961.⁴ Possibly the first teaching programme in Britain based on these principles was the "Sheffield Plan,"⁵ introduced from 1956 onwards. Psychiatric teaching in the clinical curriculum there was said to have two tasks: to bring home to the student the ubiquity of psychiatric problems, and to enable him to acquire some familiarity with psychiatric illness comparable to his knowledge of physical illness.

The objectives of psychiatric education and students' interest in psychiatry were discussed in a series of articles in an educational number of the *B.M.J.* four years ago⁶⁻⁹ as well as elsewhere. Has anything come of this campaign? Surprisingly, more than might be expected from the usually slow pace of change in medical education. Several new chairs of psychiatry have been established in this country during the last few years, and in the 1967 Recommendations as to Basic Medical Education of the General Medical Council¹⁰ psychiatry has for the first time been given the status of a major clinical subject. The need for the study of human structure and function being combined with the study of human behaviour has been stated more explicitly than before. A clinical clerkship in psychiatry with obligatory residence in hospital has been declared essential. The total period of clinical clerkships recommended is "not less than 18 months," an extension by three months over the 1967 Recommendations. In some medical schools a three-months clerkship in psychiatry is being introduced.

The incorporation of a new major subject into both the preclinical and the clinical course will require more than minor readjustments here and there. The General Medical Council Recommendations cannot be implemented without substantial changes in the curriculum. The Advisory Committee of the new Nottingham Medical School¹¹ has wholeheartedly adopted the new policies and recommended that the teaching of the behavioural sciences should run as a thread throughout the

preclinical and clinical courses. It should be the responsibility of a subcommittee of the curriculum committee chaired by the professor of psychiatry, with representatives from the departments of psychology, physiology, the social sciences, and community health. It will be interesting to watch how Nottingham, unfettered by established traditions and vested interests, will tackle this task. Here is a rare opportunity for starting something new and exciting.

Now that an official policy on the teaching of the behavioural sciences and psychiatry has been laid down, the problem of what to teach and how to teach it is in the forefront of discussions. Deeply established attitudes in the teachers, as in anyone, tend to influence their predilections. Psychiatrists are, like other doctors, the products of their medical education, which taught them mainly to recognize and to treat physical diseases. H. J. Walton and J. Drewery¹² have shown that there are several distinct types of psychiatric teachers differing in their preferences for the subjects to be emphasized in the teaching of medical students. A. C. Woodmansey,¹³ for instance, wants the teaching to be focused on child and family psychiatry because it looms large in general practice and is fundamental to prevention. Such teaching, he argues, requires the student to have first-hand experience in diagnostic-therapeutic interviews and to be taught the principles of psychotherapeutic management. Similar views were expressed by M. Balint¹⁴ and R. F. Tredgold¹⁵ some years ago. Other teachers emphasize the descriptive aspects of mental disorders. Such diversity of approaches is inevitable and can be stimulating for the student provided no one approach monopolizes the whole of the teaching programme.

Differences in teachers' and students' attitudes to the organic and psychological aspects and causes of behaviour are unlikely to be due to their medical education only. Personality factors play an important part. This has been shown by Walton, Drewery, and G. M. Carstairs⁹ in a study of students' interests in social and emotional factors of illness. Walton¹⁶ has also studied the effects of different teaching methods. He set out to test experimentally the relative merits of teaching by lecture and seminar as methods of psychiatric instruction. Contrary to expectation, students taught by lectures did not gain more factual knowledge than students taught in seminar groups. In all other respects which mattered educationally, seminar group teaching proved superior. So students will in future be able to support their demands for fewer lectures and more seminars with experimental evidence—unless something is done about the quality of lecturing which should change students' attitudes towards

it. Psychiatric lectures came out with credit in another Scottish medical school when a multiple-choice examination was used as the measuring instrument.¹⁷ In a recent American study¹⁸ the response of newly graduated doctors to their psychiatric training received in medical school was assessed with the help of a questionnaire, but only 110 of 329 interns and residents replied. Of these, 20% considered psychiatry the poorest taught subject and 19% the least learned subject. Only surgery had a poorer rating. Though the results of this study are difficult to interpret, if only because of the poor response to the inquiry, they at least show that psychiatry was in good company.

L.S.D. and Chromosomes

Despite the use of lysergic acid diethylamide (L.S.D.) both for therapy and for illicit self-administration our knowledge of its toxic effects is incomplete. In addition to the drug's acute and unpredictable hallucinogenic actions¹—leading in some instances to permanent mental damage—it has now been suggested that L.S.D. has powerful cytogenetic effects. The great majority of people who take the drug are young, so that information on this action is needed with special urgency. Is L.S.D. as dangerous as thalidomide, and, if so, what is the evidence?

The first reports of genetic effects appeared earlier this year in *Science*. M. M. Cohen and his co-workers² in Buffalo added L.S.D. to cultured human lymphocytes in doses varying from 100 µg./ml. to as little as 0.001 µg./ml. for periods varying from 4 to 48 hours. The doses of 100 and 50 µg./ml. killed the cells and arrested mitoses. All other treatments (with the exception of that with 0.001 µg./ml. for four hours) resulted in at least a twofold increase in chromosome breakage compared with controls. The types of chromosome aberrations seen included dicentric and acentric fragments, chromatid exchanges, and chromatid breaks. Cohen's team showed similar damage to chromosomes in a patient who had been given L.S.D. 15 times between 1960 and 1966 in doses varying from 80 to 200 µg. The study was carried out eight months after the last treatment.

More recently workers from Oregon³ have found similar chromosome damage in eight users of L.S.D. who had received between 4 and 200 doses with a mean estimated dose of between 200 and 600 µg. Again, chromosome and chromatid breaks and exchanges were seen. In two users there were repeated findings of a chromosome resembling the Philadelphia (Ph¹) chromosome seen in cells of patients with chronic myeloid leukaemia.⁴ L.S.D. has also been shown to cause abortion, stillbirth, congenital malformation, and reduced litter size in rats injected with the drug early in pregnancy.⁵ The same study showed that some of the surviving progeny developed less well than did controls.

Much more work is needed to study the effects of L.S.D. on the chromosomes and on mutations, as well as to assess its teratogenic danger. At this stage, however, it can be stated with certainty that L.S.D., as well as being a potential risk

to the mind of the user, may also cause chromosomal abnormalities, foetal malformations, and possibly leukaemia.

These reports raise the question whether the screening of drugs introduced therapeutically or illegally is yet adequate. Is sufficient care being taken with a new drug to determine not only its teratogenic potential but also its potentialities as a chromosome-breaking agent and mutagen? In-vitro techniques are now sufficiently developed for these tests to be carried out. How many drugs in use today have similar effects to L.S.D. and how many have been tested?

Getting on Their Nerves

It has recently been pointed out that about half of the cases of peripheral neuritis seen by the neurologist are of unknown aetiology.¹ Drugs and poisons that may give rise to a neuropathy range from isoniazid prescribed by doctors to podophyllin (American mandrake) sold by herbalists to young women suffering from amenorrhoea.² Lead and arsenic are well known as occasional causes of peripheral neuritis. Now an article by Drs. T. O. Garland and M. W. H. Patterson in the *B.M.J.* this week at page 134 draws attention to another cause of peripheral neuropathy with probable signs of central disturbances.

Acrylamide is a white crystalline solid with no significant volatility. As a biologically harmless polymer it is familiar to engineers and biochemists. The former waterproof soils with it so that tunnels may be constructed under rivers and mines sunk through water tables; biochemists use small quantities to separate proteins. In another form the polymer is used to flocculate particles so that, for example, the same water may wash successive heaps of coal. The users of the polymer are safe and so are those who make the polymer from acrylamide under reasonably good hygienic conditions. However, when the men handling the white acrylamide powder in large bags work under poor conditions where they cannot carry out simple measures of personal hygiene, an insidious condition can develop which neither they nor their family doctors may recognize as being a result of the work they are doing. Indeed, one case of acrylamide poisoning was recognized by Garland and Patterson only in a work-place as they watched the man trying to open a bag with his knife.

That work with acrylamide might produce a neuropathy had been suggested by the first scientific study of the compound by A. S. Kuperman.³ He drew attention to its extraordinary cumulative action, for in cats it could produce a similar condition whether it was given as a single dose of 50 mg./kg. body weight or 50 daily doses of 1 mg./kg. This chronic cumulative effect has since been shown to occur in other species.^{4, 5} Detailed studies of poisoned rats have shown the lesion to be a "dying back" process similar to that discussed by J. B. Cavanagh,⁶ and it is the large-diameter motor fibres that appear to be the most sensitive to the toxic effect of acrylamide.⁵ In rats doses spread over days or even weeks could eventually produce clinical evidence of neurological

damage.⁵ Fortunately in man, as in animals, the condition is slowly reversible after exposure ceases, but it is not yet possible to say whether recovery will be complete in severely affected patients. While there is no information yet on the biochemical disturbances which this relatively simple compound produces in the nervous system, it seems likely that its mode of action will be studied in the hope that more will be learnt about the metabolic processes essential to the maintenance of healthy neurones.

If ever there was good experimental evidence to warn users that a substance might be a chronic cumulative poison, the case of acrylamide seems outstanding. Perhaps the principal manufacturers believed that everyone would use it with the care they had exercised in making it after they had encountered a few cases among their workers. Yet, notoriously with chemical poisoning, it is the user and not the maker who is liable to meet trouble. Garland and Patterson conclude that acrylamide poisoning "is a relatively easy hazard to contain." Not only have some users failed to contain the hazard but neither do they seem to have appreciated that the disability suffered by some of their employees handling the substance had resulted from exposure to it.

The immediate lesson of Garland and Patterson's report is that doctors should never fail to make detailed inquiries into the occupation of their patients who present with unusual illnesses, though clearly many cases of illness (for example, neuritis or leukaemia) that may be related to a man's work are not necessarily so. The point about acrylamide poisoning is that the clinical course is unusual compared, for instance, with the Guillain-Barré type of peripheral neuropathy.

Acrylamide poisoning has been seen in the U.S.A., and published accounts, referred to by Garland and Patterson, are available from Japan and Canada as well as Great Britain now. The main lesson to be learnt is that simple hygiene is essential in every chemical plant. In most cases this is all that is needed to prevent poisoning. When so much attention is paid to the establishment of magical figures known as M.A.C.s (maximum allowable concentrations) for atmospheric contaminants, surely employers in this country, which led the Industrial Revolution, might pioneer the Industrial Safety Revolution by providing the means and encouraging the discipline necessary for the protection of employees from injury.⁷

Dysmenorrhoea

Few women menstruate without some degree of discomfort, but it is only when this discomfort becomes sufficiently severe to warrant treatment that the diagnosis of dysmenorrhoea is made. Primary dysmenorrhoea—also called congenital or essential—affects the young girl, occasionally as soon as she starts menstruating, but usually within a year or two of starting. Secondary, congestive, or acquired dysmenorrhoea describes painful periods which are the result of local disease such as infections, fibroids, or endometriosis. The condition arises in later life and the treatment is of the underlying cause. Where no underlying cause can be found, then treatment should be given on the empirical lines which are used for primary dysmenorrhoea.

In the primary or spasmodic type of dysmenorrhoea there is apparently no underlying pathological condition, though in some cases hypoplasia of the uterus or stenosis of the cervix

⁷ *Brit. med. J.*, 1967, 3, 507.

is blamed. In some cases of primary dysmenorrhoea there may be psychogenic overlay or a low threshold of pain,¹ but this is probably not the whole explanation. J. Chassar Moir² found that patients with dysmenorrhoea felt pain when the intrauterine pressure exceeded their own blood pressure. This ischaemic type of pain would be expected to last for longer than the duration of the single contraction of the uterus, and indeed the pain of dysmenorrhoea has two components: the colicky part due to contraction and the prolonged part due to ischaemia.

Other theories of causation for primary dysmenorrhoea have been advanced. On the basis of histological studies of the endometrium the condition has been attributed to an imbalance in the oestrogen-progesterone equilibrium, but this has not been confirmed when assays of these hormones in the blood and urine of women with dysmenorrhoea have been done. It has also been postulated that an excess of progesterone could cause overdevelopment of the endometrium and also that progesterone causes high tone in the isthmus and upper part of the cervix. The belief that progesterone can cause dysmenorrhoea is strengthened by the fact that anovulatory cycles are painless. However, a progestational agent, dydrogesterone, has been shown³ to be effective in the relief of dysmenorrhoea, though it does not suppress ovulation.

A measure of our continuing inability to understand the mechanisms underlying primary dysmenorrhoea is reflected in the form of treatment in use. Among the many suggestions made recently by G. C. Schauffler⁴ in a symposium on paediatric and adolescent gynaecology are physiotherapy, hot Sitz baths, and diathermy. He found exercise relatively valueless and hypnosis surprisingly effective. Schauffler scorns the use of hormone therapy but still advocates dilatation of the cervix without mentioning the possible risk of causing incompetence of the cervix.

Another approach to the problem has been made by N. L. Warren and R. W. Hawker,⁵ who found that blood obtained from girls suffering from dysmenorrhoea contained less oxytocin than normal. They postulate that oxytocin has a regulatory function in the control of menstrual uterine contractions and that a low level of oxytocin could give rise to contractions associated with dysmenorrhoea. Certainly intramuscular injections of oxytocin have been shown to relieve dysmenorrhoea.⁷

The underlying cause of dysmenorrhoea remains obscure and treatment is variable. In the past it was believed that all that was required to prevent dysmenorrhoea was a "healthy outlook," plenty of exercise, and fresh air; and though this view has died out a healthy psychological outlook and attention to exercise and hygiene are nevertheless still important. When treatment with drugs is required it is usual first to try the effect of a simple analgesic such as aspirin, possibly combined with an antispasmodic, phenobarbitone, meprobamate, or amphetamine. If these relatively simple procedures are unsuccessful then recourse to hormone therapy is the next step. This can be done either by giving dydrogesterone 5 mg. b.d. from the fifth to the twenty-fifth

day of the cycle or by using one of the contraceptive pills to suppress ovulation. Dilatation of the cervix is less commonly performed nowadays and the drastic approach of presacral neurectomy is fortunately very seldom if ever required now. It is important to avoid drugs with a potential for addiction. Each practitioner acquires his favourite forms of therapy and rings the changes as and when required, but the simplest and safest is best.

Westward Ho!

Nobody who reads last week's report¹ on the "brain drain" can doubt the validity of its conclusion: "This is now increasing to such an extent that it constitutes a threat to the interests of this country." A report by the Royal Society² on the emigration of Ph.D.s evoked much the same comment in these columns³ four years ago, but in the interval more evidence has accumulated—and the emigration accelerated.

Though the present report excludes the medical and allied professions, it may be pertinent in several ways to the emigration of doctors, and the scientists whose departure it does discuss doubtless include among their numbers some whose work has a bearing on medicine. In round figures the numbers of engineers, technologists, and scientists emigrating for at least a year from the United Kingdom rose from 3,200 in 1961 to 6,200 in 1966. Some will return, but the report holds out little hope that many will, for it goes so far as to state that "this trend could have disastrous consequences for British industry and the economy within ten to twenty years if it were to continue at the present rate." Though the emigration of scientists might be less disturbing in the short term than that of engineers and technologists, the report considers that in the long term "it throws light on attitudes which are developing and whose consequences could be serious for our capacity as a nation to hold our own in the advance of science-based industries." It is not difficult to foresee that the development and practice of medicine must likewise suffer great harm if the emigration of the profession's energetic and able younger men continues in the way it has done for some years.

Most of the emigrants go between the ages of 25 and 35, and since the report rightly excludes any idea of imposing restrictions to stop them it looks for reasons why these highly qualified people, exceptionally favoured to compete for professional advancement in their own country, make their career elsewhere (mostly in North America). But since the motives for emigration are often complex and sometimes only half recognized by the emigrant himself any information obtained by questioning is apt to be difficult to interpret. According to the report North America is thought of as a "young man's country" where ability counts more than age, experience, or seniority. The standard of living is attractive, and though British taxation as such is not believed to be a prime motive for leaving the country it is thought to have more influence in deterring emigrants from coming back. What is believed to be a "cause of much malaise" is the

extreme difficulty confronting the salary earner in Britain of accumulating any capital. Both entrenched privilege and economic egalitarianism are believed to be aspects of the British scene that emigrants dislike. The views of British physicians who had emigrated to North America were analysed recently by T. C. Gibson,⁴ and though expressed in somewhat different terms they have many points of resemblance with those recorded in last week's report. The three main factors influencing their decision to emigrate were dissatisfaction with opportunities for promotion, the lure of better economic conditions, and dissatisfaction with conditions of work in the United Kingdom. On a specific question whether the decision to emigrate was influenced by conditions in the National Health Service Gibson found that the replies were evenly divided between yes and no.

The report's approach to halting the brain drain is, through a number of recommendations both to the Government and to industry, to try to make prospects in Britain so attractive that young people will prefer to remain here than to seek their fortune overseas. This surely is the right way, for medicine as well as for the non-medical occupations now reported upon. As much the largest employer of doctors, the Government has a special responsibility to make conditions of employment attractive if the present damaging flow of talent abroad is to be reduced to healthier proportions. And senior members of the medical profession too, especially those in a position to mould the future course of medical practice, have a responsibility to see that their juniors have decent prospects and opportunities.

Surgery in Pulmonary Tuberculosis

There are two main reasons for the recent decline in the necessity for surgical treatment of pulmonary tuberculosis. Firstly, the development of effective antituberculous chemotherapy has undoubtedly played the major part, and, secondly, there has been a notable improvement in general living conditions. Nevertheless, there is still a small but definite place for surgery in the treatment of pulmonary tuberculosis,¹ and this is likely to remain so as long as the disease is present.

The few patients who still require surgical treatment to complete their recovery fall roughly into six groups. The first of these are those patients with cavitated disease who after six months of adequate chemotherapy are still producing positive bacillary tests, particularly where the original organism showed an appreciable degree of resistance to the standard antituberculous drugs. After a period of unsuccessful treatment the risk of the development of resistance increases steadily, while the patient's acceptance of his treatment—as well as the doctor's enthusiasm—may be sorely tried. Resection while antituberculous drugs are still effectual should therefore be carried out in these cases after the chest physician and thoracic surgeon have discussed all the factors concerned. The drugs should be continued after operation for three months to one year according to the severity of the disease.

The second group comprises those patients who have an undiagnosed nodular lesion on the chest radiograph, particularly those over the age of 40. Frequently it is possible to make a differential diagnosis only of tuberculosis, carcinoma, or a lesion such as hamartoma, and hence resection should be carried out. If the lesion is found to be tuberculous the

patient's antituberculous chemotherapy should be continued, and he should be allowed to return to his normal activities fairly rapidly.

The third group contains those patients who are left with troublesome residual damage from earlier pneumothorax therapy, or from other forms of collapse therapy such as plombage. Here the problem is usually that of an empyema, and often even many years later tubercle bacilli can be recovered from the fluid. Hence these lesions should be removed, and total pleurectomy may well be needed. The fourth group of patients who may need operation are those who suffer from repeated or severe haemoptysis. This usually originates from bronchiectatic lesions, though the actual tuberculous process is frequently quiescent or healed. Similarly a few patients with "healed cavities" which have become secondarily infected with *aspergillus* fungus may also need surgery.

There is also the rare occurrence of the patient who gets recurrent attacks of pneumonitis and pleurisy secondary to a localized bronchostenosis, which can be treated only surgically. Temporary antituberculous chemotherapeutic cover during, and a few weeks after, operation (which is usually a conservative resection) is advisable.

Sometimes the thoracic surgeon may be asked to consider early resection of a tuberculous lesion for what is said to be a social or occupational reason. This fifth group may include patients, such as alcoholics or those with mental illness, whose attendance at hospital is likely to be irregular, and occasionally patients such as seamen, who, if unwilling to submit to treatment, are apt to cause cross-infection in enclosed communities. Nevertheless, this indication should be accepted only with considerable reserve, as modern chemotherapy is adequate to deal with these lesions, and the patient should be pressed to co-operate for the necessary time. This indication varies widely from unit to unit and is probably a commoner indication for surgery in the United States, as H. T. Langston and his colleagues² have pointed out.

Lastly, there is a small group of patients who have tuberculous disease of the lungs in association with other diseases—such as cancer or congenital heart disease—and its treatment may present special problems and require early operation.

The standard methods of diagnosis and investigation of patients with pulmonary tuberculosis have been unaffected by the decline in the amount of surgical treatment. Nevertheless, bronchoscopy is still an important investigation in any patient who requires surgery. The number of cases of endobronchial lesions reported is now extremely small owing to efficient drug therapy, but it is still important that these should be looked for before surgery is carried out. The commonest operations used are still lobectomy or segmental resection of the lung for localized tuberculous foci, and occasionally pneumonectomy is needed for widespread tuberculosis, and—particularly if the pleura is involved—pleuro-pneumonectomy is required as well. Nevertheless, thoracoplasty still has a place, particularly in patients who are left with upper lobe cavitation, a positive sputum and possibly an organism resistant to several of the available agents, and, last—but most important—a limited lung reserve. A combination of resection and a limited thoracoplasty is sometimes valuable in the treatment of upper lobe lesions, either performed at the same time or more usually with the resection first and the thoracoplasty second. The indication for this procedure is

¹ Langston, H. T., Barker, W. L., and Pyle, M. M., *Ann. Surg.*, 1966, 164, 567.

² Chesterman, J. T., *Thorax*, 1957, 12, 159.

usually a persistent air space or the risk of emphysema developing in the residual lobe of the lung, or an exacerbation of the disease in the lobe.

A rare but associated problem to that of pulmonary tuberculosis, which arises particularly in children, is the treatment of tuberculous mediastinal glands. These can enlarge and press on or ulcerate into the bronchus. Repeated piecemeal bronchoscopic debridement is often required to restore the bronchial lumen and maintain normal lung function beyond it. If bronchoscopic aspiration is unsuccessful with a florid primary tuberculous infection of this type, thoracotomy and excision or evacuation of the glands may be required. This procedure is particularly valuable in preventing irreversible damage in the peripheral bronchi beyond the narrowed area.²

Langston and his colleagues have drawn attention to the recent increase in the study of atypical mycobacteria, which has resulted largely because of the greatly increased use and refinement of cultures for studying sputa. These organisms present varying problems of sensitivity, and in their view surgical intervention may have to be accepted earlier in patients infected by atypical organisms than in ordinary cases of infection with *Mycobacterium tuberculosis*.

The aim of surgery in pulmonary tuberculosis is still to be as conservative as possible; and careful preoperative investigation and proper surgical technique should enable the minimal amount of lung to be removed to achieve a satisfactory end result.

No Change

In these times of opinion polls and "random" surveys there is something refreshingly solid and reliable about a ballot. At the Annual Representative Meeting in 1966 the principle of merit awards was under discussion and it was resolved¹ "that a postal ballot should be undertaken of all consultants and senior hospital staff and senior registrars to ascertain their views in respect of merit awards for consultants." The results are published at p. 22 of this week's *Supplement*.

The overall impression given by the response to the questions asked is that senior hospital staff are satisfied with the present system of merit awards. Despite considerable publicity in the *B.M.J.* and the *Lancet* only half the doctors concerned took part in the investigation. Not surprisingly, 95% of those with awards who replied were in favour of their continuation, though nearly half of them thought some changes were needed in the system. Even of those without awards 65% favoured their retention; but 80% of this group thought changes should be made in the system of distribution. The ballot papers asked what changes in the system were desirable. Though many comments were made there was little agreement on what features needed reform. Secrecy was the most popular subject for comment—but even here only a fifth of those replying mentioned it. The form of the questions may have caused doctors some difficulty, and the 50% poll detracts from the results, but nevertheless most hospital doctors in the senior grades seem happy with the system of merit awards, and no feature is widely disliked. The constructive comments should not be ignored: but if democratic principles mean anything this ballot has produced a mandate for "no change."

¹ *Brit. med. J. Suppl.*, 1966, 2, 60.

Stanley Morison and the B.M.J.

Mr. Stanley Morison, who died last week at the age of 78, was a typographer of world-wide renown; designer of the type-face known as Times New Roman, now used extensively in the printing of books, periodicals, and newspapers throughout the civilized world; at one time editor of *The Times Literary Supplement*; and the principal architect and author of the monumental five-volume *History of The Times*—"the solid historical and political foundations on which the whole structure rests were due to his astonishing (because it seemed to be effortless) power for research," to quote from the obituary in the newspaper whose history he helped to mould as well as record. Stanley Morison was a great scholar and a great man who profoundly influenced those fortunate to know him. His contributions and distinctions were recorded in the biography published in *The Times* last week. What may be not well enough known is the part he played in the history of the *British Medical Journal* when his advice as a typographer was sought in 1935. It is therefore fitting that we should report at this time some of the facts of his beneficent intervention in the affairs of a periodical which thirty years ago looked—to use the description he then gave to the Journal Committee—more like the boiler-makers' magazine than the weekly journal of a learned profession. The rich overtones of his laughter as he passed this apt judgement removed all possible offence from it.

The scene on which Morison appeared in 1935 was one of some concern about the affairs of the *B.M.J.*: about its contents, its circulation, its physical appearance, and about the method of printing it and methods of management. It was not long before Morison had persuaded the Journal Committee that in the approaching reform the sham Gothic of the title on the cover should go. From that as a starting-point he went in detail through the whole of the *B.M.J.*, relating the changes he proposed to the significance of its different sections. He was soon invited to turn his attention to the various operations of producing the journal, and increasingly his advice on them was taken. A turning-point in this investigation was his recommendation that the composing-room immediately above the editorial offices should be abolished. The Council of the B.M.A. finally, after much debate and some close voting, accepted the Journal Committee's recommendation that this should be done, and accepted the consequences that flowed from it. And so when the *B.M.J.* made its first appearance in its new dress in 1937 the composing-room on the fourth floor of the north side of B.M.A. House was being dismantled, and the new journal was then composed and machine-printed for the first time by one and the same printer. This inevitably led to changes in managerial structure. The sum total of these changes altered the fortunes of the *B.M.J.* to the great financial advantage of the B.M.A. Many experts were consulted on the way to this radical reform. But if there is one man to whom in retrospect we may turn for special praise and thanks it is Mr. Stanley Morison. He gave the Journal Committee unstintingly of his unique experience, his wisdom, his practical sense, and his fearless integrity. This he continued to do for many years after the grand climax of the *B.M.J.*'s revolution had passed. It would, we believe, have pleased him to have in this brief commemorative tribute a few notes about a bypath in the history of journalism, one of many subjects he made his own and thereby made the world so much better informed and the richer for it.

Papers and Originals

Cancer Hazards of the Pharmacy*

GEORGIANA M. BONSER, M.D., F.R.C.P.

Brit. med. J., 1967, 4, 129-134

New therapeutic agents are constantly being synthesized and then scrutinized from the viewpoint both of their value in the treatment of disease and of their possible undesirable effects. One such effect is the induction of cancer, and I shall recount the steps which are being taken at the present time to ensure that cancer-producing chemicals are not used in the treatment of human beings. This is far more difficult than appears at first sight, for the following six reasons.

(1) The chemical structure of a compound rarely allows prediction of its carcinogenic properties. Though ideas have been suggested for a connexion between structure and activity, important exceptions to all such correlations have been found. Minor variations in molecular structure can lead to enhancement or abolition of carcinogenic activity. None the less, as new carcinogens are discovered the field of relation of chemical structure to carcinogenesis will be widened so that at least some compounds may be detected by structure alone. This argument provides a strong justification for the pursuit of studies which elicit carcinogenic activity from compounds hitherto untested.

(2) As little help can be got from chemical structure, theoretically it becomes necessary to test every proposed synthetic drug by well-planned and prolonged animal experiments. This is quite impracticable, and therefore a selection of compounds has to be made. Great efforts are in train to devise shorter screening tests for carcinogenicity, such as the use of newborn rodents or the detection of reliable precancerous changes.

(3) The time between the first administration of a carcinogen and the appearance of the tumour is a long one. In the human being it ranges from about 5 to 40 years (longer in exceptional cases); in the rat from nine months to two years. This is known as the latent or induction period.

(4) There is no need for the carcinogen to be present during the whole of the latent period. For example, Case, Hosker, McDonald, and Pearson (1954) recorded that 6 out of 281 men exposed to carcinogens in industry for six months to one year developed tumours of the bladder 10 to 25 years after leaving the industry. There are numerous examples in animals where a single dose of a carcinogen may be followed months later by the development of a tumour. Limited doses are, however, unlikely to be effective unless a subsequent latent period is allowed to elapse.

(5) Species differences in response to the administration of chemicals are very great, and therefore tumours induced in animals may not reflect what is likely to happen in man. But it is a fact that with one important exception all the *known* chemicals causing tumours in man cause tumours also in the experimental animal. The importance of species variations in response to drug administration is emphasized by Roe (1966).

(6) Little is known about the relation between the dose of chemicals and tumour induction in various species. Therapeutic doses may never attain to those required to induce tumours in animals; but we do know that small doses can induce tumours in human beings. For example, there was 0.2% of 2-naphthylamine in rubber, which could be the cause of bladder cancer in an exposed tire-maker.

In January 1964 the Ministry of Health set up a Committee on Safety of Drugs. The scheme is voluntary and the terms of reference are wide. The two which concern us are: (1) to invite from the manufacturer or other person developing or proposing to market a drug in the U.K. any reports they may think fit on the toxicity tests carried out on it; to consider whether any further test should be made, and whether the drug should be submitted to clinical trial; and (2) taking into account the safety and efficiency of each drug, and the purpose for which it is to be used, to consider whether it will be released for marketing, with or without precautions or restrictions on its use.

It is thus clear that the manufacturer is guided by the committee in the selection of drugs for carcinogenic testing. The sole means of judging carcinogenic potentiality, apart from unfortunate unwitting occurrences in man, is by tests in animals. The difficulty which arises is in the interpretation of the results of animal tests in relation to man. This is recognized as needing an expert Panel on Carcinogenesis to advise the Minister of Health.

I propose now to consider carcinogenic therapeutic agents under two headings (Table I). (1) Those of which the cancer-inducing properties were first demonstrated in man; some of these were later confirmed in animals and some not. (2) Those of which the cancer-inducing properties were first demonstrated in animals; some of these later induced tumours in man and some have not done so until the present time. Added to these are the drugs which aroused suspicion on toxicity testing and were therefore not administered to man.

TABLE I.—Classification of Carcinogenic Therapeutic Agents

- | |
|--|
| 1. Carcinogenic activity first seen in man |
| Arsenic |
| Chlornaphazin |
| X-radiation (confirmed in animals) |
| 2. Carcinogenic activity first seen in animals |
| Thorotrast (confirmed in man) |
| Iron-dextran |
| Isoniazid |
| Trypan blue |
| Griseofulvin |
| Urethane |
| Goitrogens |
| Oestrogens |
| HPA* (not given to man) |
| SADA† (not given to man) |

* 4-Ethylsulphonylnaphthalene-1-sulphonamide (anticonvulsant and diuretic).
† 2-p-Methoxybenzenesulphonamido-5-isobutyl-1,3,4-thiadiazole (hypoglycaemic agent).

Group 1

Arsenic

Neubauer (1947) collected from the literature 143 cases of skin cancer attributed to the medicinal use of arsenic, and Hueper (1957) recorded a further 37 cases. In Neubauer's

* Stewart Memorial Lecture delivered at the University of Leeds on 19 May 1967.

series the disease for which the arsenic was given was known in 125 cases. In 89 (71%) there was an underlying skin condition, psoriasis being the commonest (54%), so that in the subsequent development of the skin tumours another factor, apart from the arsenic, might have been operating as well. In only 2 of the 125 cases had arsenical treatment been given for syphilis. This is surprising, as it was the usual treatment for that disease before the advent of antibiotics. No attempt has been made to relate arsenical skin cancer in man to the size of population from which the cases were drawn. For these reasons a valid statistical evaluation of the carcinogenic properties of arsenic in man is still awaited. Many attempts have been made over the past 40 years to induce tumours experimentally in animals with arsenic and none has been successful (Baroni, van Esch, and Saffiotti, 1963). This may be due to the toxic nature of arsenic and its derivatives, which effectively precludes the administration of sufficiently large doses to animals and also shortens the life of the animals.

Chlornaphazin

Chlornaphazin (*N,N*-bis(2-chloroethyl)-2-naphthylamine) has been used, especially in Scandinavia (Thiede, Chievitz, and Christensen, 1964) for the treatment of polycythaemia vera. This compound is a mustard derivative of 2-naphthylamine, which is an important industrial bladder carcinogen, and it might be expected to yield 2-naphthylamine or its metabolites when introduced into the human body. Or the compound might act in virtue of the mustard moiety, or in both ways. The effect of the drug was favourable to the original disease in 75% of patients. Of the 61 treated patients, seven developed tumours of the bladder (five carcinomas and two papillomas), all of these having received a dose greater than 100 g. and having been treated for 2 to 11 years. Some of these patients also received treatment with ^{32}P , but it seems clear that the chlornaphazin was responsible for the induction of the bladder tumours. No more recent report has been published, but it seems probable that further cases will have emerged in the time intervening since 1964.

This drug has also been used in the treatment of Hodgkin's disease, where survival is likely to be much shorter than in polycythaemia, and at least two cases of bladder cancer have been recorded after five and six years of treatment respectively (Videbæk, 1964). Thus chlornaphazin is carcinogenic to man when given in adequate dosage for an adequate period of time. No animal experiments have been reported, but when tested this drug is certain to be carcinogenic.

X-radiation

X-radiation was first used for diagnostic purposes and occasionally for therapy at the end of the last century (Schuster, 1962). Such use caused squamous carcinomas of the skin of the exposed areas in those who worked with the rays unless rigid precautions were taken. During the years 1935-54, of 14,554 patients treated in Great Britain for ankylosing spondylitis by means of ionizing radiations (Court-Brown and Doll, 1965), a highly significant increase in mortality from leukaemia and aplastic anaemia was observed—52 actual deaths from

leukaemia (0.36%) against 5.48 deaths expected (Table II). The proportion of the myeloid over the lymphatic type was also increased.

In 1955 Simpson, Hempelmann, and Fuller showed that children who had received local irradiation for "thymic enlargement" were more likely to develop thyroid tumours than non-irradiated children. Among 1,722 irradiated children there were six thyroid cancers and nine thyroid adenomas compared with none and one respectively in 1,795 related non-irradiated children. The mechanism of this occurrence is presumably radiation damage to the thyroid gland causing the blocking of thyroxine secretion followed by excess thyroid-stimulating hormone secretion by the pituitary gland. The latter causes the remaining thyroid cells to undergo excessive growth and finally neoplasia.

Both these findings, but especially the first, demonstrate that the association between administration of a carcinogen and the subsequent development of a neoplastic condition need not be an obvious one and may need patient research in order to uncover it and advanced statistical methods to elucidate it. The chances that any single practitioner will encounter a case are remote indeed.

Group 2

Thorotrast

Thorotrast (colloidal thorium dioxide) is not strictly a drug but has been widely used in man as a contrast medium for diagnostic purposes. It was shown to induce subcutaneous sarcomas in rats and mice (Selbie, 1938) and in guinea-pigs (Foulds, 1939) following injection, the tumours being attributable to its radioactivity. Much later it was realized that tumours were occurring in man, and in 1961 Dahlgren (Table III) collected some 60 cases from the literature of which I have selected the following examples. In all, 24 tumours occurred where thorotrast had been placed in hollow organs, seven being situated in the maxillary sinus. Twenty-seven were due to the compound injected systemically, taken up in the reticulo-endothelial system and deposited chiefly in the liver, spleen, and bone marrow. Though the compound was administered at sites distant to those of the tumours, the latter must be regarded as due to the local presence of the radioactive material in the affected organs. The variety of induced tumour was very great, the commonest being in the liver—hepatomas, bile-duct carcinomas, or haemangioendotheliomas. The induction period was 6 to 35 years. In many cases this could be calculated exactly, as only one dose was given. No tumours were recorded in bone. An unusual tumour was a carcinoma of the kidney occurring after cerebral angiography. No estimate can be made of the total number of thorotrast-treated patients from whom these cases were drawn, and to establish cause and effect with certainty this information is necessary. However, it was possible to demonstrate radioactive material in the vicinity of the tumours in many cases.

TABLE III.—*Examples of Tumours in Man Induced by Thorotrast (Dahlgren, 1961)*

Mode of Origin	Procedure	Nature and Site of Tumours	Range of Latent Period (Years)
At site of injection	Cerebral angiography (1)	Sarcoma	6
After deposition in pre-formed cavities	Pyelography (7)	Sarcoma } Kidney	16-25
	Maxillary visualization (7)	Carcinoma sinus	10-21
	Dacryocystography (1)	Carcinoma eyelid	35
	Hepatolienography (9)	Sarcoma } Liver	12-24
After systemic injection	Arteriography (13)	Sarcoma } Liver	12-24
	Cerebral angiography (1)	Carcinoma } Liver	20
		Carcinoma kidney	

TABLE II.—*Two Examples of Post-irradiation Tumours in Man*

Disease Treated	Irradiated Patients		Non-irradiated Patients	Tumour Deaths		Latent Period (Years)
	Years	No.		Treated	Control	
Ankylosing spondylitis	1935-54	14,554		52 leukaemias	5.48 (expected)	5-25
Thymic enlargement	1925-51	1,722	1,795	6 thyroid carcinomas 9 thyroid adenomas	0 1	5-15

Iron-dextran

Iron-dextran (Imferon) has wide use in man as a means of supplying parenteral iron. It is a complex of colloidal ferric chloride and a dextran of low molecular weight. It has been found to induce sarcomas on intramuscular and subcutaneous injection into rats, mice, and hamsters (Richmond, 1960; Haddow and Horning, 1960) and rabbits (Haddow, Roe, and Mitchley, 1964). The latent period was 12 months or more in rodents and three to four years in rabbits.

The experimental doses were large in relation to the size of the animals, but Roe, Haddow, Dukes, and Mitchley (1964) argued that "since the size of body cells is similar in man and laboratory animals, the actual dose, and not the body weight, may be the critical factor in determining the induction of tumours . . . a particular volume of material will come into contact with approximately the same number of body cells in the rat as it does in man." They then conducted an experiment directed to finding out "whether the incidence and time of appearance of tumours in rats given a fixed number of injections of iron-dextran would be affected by distributing the injections between 2, 4, or 6 sites, instead of giving them, as in previous experiments, all into the same site." This is important from the viewpoint of clinical use.

Twenty-four subcutaneous injections of 0.5 ml. were given to each rat, all in the same site in group 1 and distributed among six sites in group 4 (Table IV). It is seen that increasing the number of injection sites does reduce, but does not abolish, the chance of tumour development at any one site and does delay the date of their appearance. It also decreases their malignancy. However, it is to be noted that as little as 2 ml. of iron-dextran induced 12% of tumours at 75 weeks.

TABLE IV.—Iron-dextran Tumour Incidence After Subcutaneous Injection at One or More Sites (Rat)

Group:	1	2	3	4	5
No. of rats	24	24	24	24	24
No. of injection sites per rat	1	2	4	6	0
Total amount injected at each site (ml.)	12	6	3	2	0
Time of appearance of first malignant tumour (weeks)	47	66	64	75	—
Injection sites with tumours	14/22 64%	11/46 24%	29/96 30%	17/138 12%	0

It is suggested that in order to exert a carcinogenic effect an excess of heavy metal must be present, and this could lead to oxidation of sulphhydryl groups and in turn to gross disturbance of enzyme systems in adjacent cells. Whatever the mechanism, the local excess of iron seems to be important. The role of dextran may be to aid penetration of iron into the cell.

No tumours have yet been reported in man, but patients will need to be followed for 15 to 40 years before they can be regarded as safe. The accumulation of iron in human tissues has been suggested as carrying a carcinogenic risk—for example, the hepatomas found in haemochromatosis and the carcinomas of the bronchus in iron-ore miners (Faulds and Stewart, 1956). Stewart (1931) could not satisfy himself that the former was the case, though other authors have been more positive, but he accepted the association between iron-ore mining and lung carcinoma.

Isoniazid

As a most useful therapeutic adjunct to streptomycin in the treatment of tuberculosis isoniazid has proved its worth. Since 1957 it has become increasingly clear that this drug is carcinogenic in the experimental animal (Biancifiore and Severi, 1966). Pulmonary adenomas and carcinomas have been induced by oral and other administration to mice (Table V). Furthermore, hydrazine (a hydrolysis product of isoniazid) caused pulmonary tumours and hepatomas in mice, but isonicotinic acid was

much less effective. A derivative of hydrazine (Natulan) caused mammary tumours in male and female rats; hydrazine sulphate caused lung tumours in rats (Biancifiore, Giornelli-Santilli, Milia, and Severi, 1966). It is suggested that isoniazid acts by virtue of its hydrazine component.

TABLE V.—Induction of Tumours by Isoniazid and Derivatives in Mouse and Rat

Compound	Species	Sites of Tumours
Isoniazid	Mouse	Lung. Lymph nodes Lung. Liver Lung (a few)
Hydrazine sulphate		
Isonicotinic acid		
Natulan	Rat	Breast (male and female) Lung
Hydrazine sulphate		

No tumours have been reported in man following the prophylactic or therapeutic use of isoniazid, and it will be unusually difficult to demonstrate such an association because virtually all tuberculous patients receive the drug and so there is no comparable untreated population to evaluate. Hammond, Selikoff, and Robitzek (1967) have attempted an evaluation of the effects of isoniazid in the 16 years since the introduction of therapy with this drug in 1951. In a series of several thousands of tuberculous males and females, some of whom may have been given isoniazid, there was a slight excess of lung cancer compared with the general population in males but not of a magnitude to be regarded as significant. Of a much smaller series of tuberculous patients treated with isoniazid there was no excess of lung cancer in the few who have died, nor was there any suggestion of a dose-response relationship. Of a series of pregnant women treated prophylactically, together with a scrutiny of their offspring (some of whom had attained an age of 13 years) there was again no evidence of an increase in lung cancer. This investigation is still in progress, and though the results are reassuring so far they cannot be expected to give the complete answer regarding the carcinogenic effects of isoniazid in the human being.

Ferebee (1965) has been undertaking since 1955 an investigation of the carcinogenic effects of isoniazid used prophylactically in 70,000 persons ranging in age from 2 months to 100 years. This author argues that a comparison of lung cancer incidence in treated tuberculous patients with that of the general population would not be valid because (1) tuberculosis may predispose to lung cancer; (2) tuberculous patients receive extra radiation for diagnostic and therapeutic purposes; and (3) tuberculous patients may smoke more and they usually belong to selected poorer social groups. Therefore the control population for this investigation is derived from a group of subjects given a placebo in place of isoniazid. The results are not yet available.

An additional difficulty in assessing the effects of the drug is that only a small number of patients treated with isoniazid, with or without tuberculosis, come to necropsy, and in those that do the past history is often not known. None the less, the starting-point of all the work which has been done on these compounds was the observation of Berencsi, Entz, and Vajkoczy (1952) that in a patient being treated with isoniazid presumptively for tuberculosis, but actually suffering from carcinoma of the lung, the clinical course was extremely rapid owing to precocious, numerous, and voluminous metastases due, it is suggested, to the enhancing effect of the isoniazid.

Trypan Blue

Trypan-blue has been used in man, by intravenous injection, for the estimation of blood volume and also to demonstrate the lymphatic pathways in block dissection of lymph nodes. Gillman, Gillman, and Gilbert (1949) gave intravenous injections of 10 mg. of trypan blue in water to pregnant rats and induced malformations in the offspring resembling those caused by rubella in the human being. They then continued the experiments in the same mothers, and in new females and males,

giving a total of 100–200 mg. of the chemical to each animal. They obtained a high yield of reticulum-cell sarcomas in the liver, smaller numbers of spindle-cell sarcomas, and many lymphomas and proliferations resembling Hodgkin's sarcomas in nodes. The latent period was less than a year. They found that the dye was bound to plasma albumin and then taken up by reticuloendothelial cells throughout the body, but especially in the liver. They were able to demonstrate spindle-cell sarcomas in the liver after a single injection in as short a period as 19 weeks. They found also that Evans blue had a similar action in causing liver tumours. They made the very interesting observation that although trypan red and Congo red do not cause proliferation of the reticuloendothelial cells in treated mothers, Congo red causes malformations in the offspring. Thus trypan blue is carcinogenic and teratogenic, and Congo red is teratogenic but not carcinogenic, and trypan red has neither action. Obviously much more information about the effects of these compounds is needed.

Griseofulvin

Griseofulvin is an antibiotic derived from three types of *Penicillium* (*P. patulum*, *P. griseofulvum*, and *P. janczewski*) and is extensively used in the systemic treatment of superficial fungal infections in man and animals. When it is administered orally and continuously to mice (Weston Hurst and Paget, 1963) this drug causes derangement of the porphyrin mechanism so that protoporphyrin is deposited in large quantities in the liver. Consequent on this, liver-cell necrosis, bile-duct proliferation, and cirrhosis occur, followed by the induction of multiple hepatomas. If the conditions of the experiment are such that the protoporphyrin can be eliminated from the liver—for example, if the dose is small or discontinuous—the liver damage and tumours do not occur. It could be postulated that continuous absorption could take place in treated patients, but the amount absorbed would be unlikely to reach a sufficient dimension to cause the damage seen under experimental conditions. No tumours have been reported in man or in the veterinary field. It is of significance that other mould products, such as aflatoxin derived from *Aspergillus flavus*, are potent liver carcinogens.

Urethane

Urethane, which induces lung tumours in rodents, has the property of initiating tumour formation in mouse skin even when administered orally, but requires the topical administration of a co-carcinogen to render the tumours manifest. It has been virtually abandoned for therapeutic use as more efficient tumour chemotherapeutic agents have been found.

Goitrogens

Goitrogens act by a feedback mechanism similar to that described in thymic irradiation. When given orally they cause carcinomas of the thyroid gland in rodents. The incidence can be increased and the malignancy enhanced by combining the short-term administration of a known chemical carcinogen with subsequent administration of the goitrogen (Bielschowsky, 1945).

Oestrogens

Oestrogens, by whatever route administered, cause mammary carcinomas in mice, but only if other factors such as a virus or progesterone are also present.

The work of Court-Brown and Doll (1965) has emphasized how advantageous is a large population in demonstrating a

carcinogenic risk in treated patients. This would apply also to those treated with goitrogens and oestrogens, but so far no large series has been analysed from the point of view of cancer induction. The small amount of evidence available does not suggest that these compounds have induced tumours in man. Another factor is present, however, in the use of synthetic and semisynthetic hormones. Apart from their cancer-inducing potentialities due to their hormonal action they may induce tumours, especially of the liver, by virtue of their chemical structure. A large-scale trial of the long-term effects of synthetic oestrogens and progestins has been initiated in the introduction of the contraceptive pill, and information will certainly eventually become available in regard to the presence or absence of tumour-inducing properties in these compounds in man. Meanwhile straws are blowing in the wind. Poel (1966) found an enhanced incidence, earlier onset, and more rapid development of pituitary tumours in female mice treated with progestins than in virgin controls (Table VI). But old breeding mice of this strain in another laboratory developed many pituitary tumours, so that the meaning of this experiment is far from clear. He also found 10 hepatomas in 96 treated mice and none in the controls, but unfortunately gave no further details.

TABLE VI.—Pituitary Tumours in Mice Treated with Progestins (after Poel, 1966)

Compound	Daily Dose	Tumours in Survivors to 85 Weeks or More	Approximate Size (mm.)
50 parts norethynodrel and 1 part mestranol	70 µg.	7/7	2–7
	7 "	6/11	1–5
50 parts norethindrone and 1 part ethinyloestradiol	70 "	5/8	2–4
	7 "	7/15	2–6
Control	None	2/15*	<1–1

* Killed at 90 weeks.

Cahal (1966) referred to experiments by manufacturers of oral contraceptives and concluded that "mestranol, when administered in high doses and for prolonged periods to rats, causes liver damage which is sometimes severe, including on occasion the development of hepatomas. Adequate experiments have not been carried out on other species of animals."

Stoll (1967) used Lyndiol (a contraceptive pill containing ethinyloestrenol as progestin and mestranol as oestrogen) in the treatment of breast cancer in postmenopausal women. He found disordered liver function, jaundice, or hepatic necrosis on biopsy in 15 of 38 patients, apparent at the contraceptive dose of one tablet a day but more marked when the dose was increased to six tablets.

It would be very reassuring to learn of negative results in well-conducted long-term experiments in animals before the human experiment has assumed too great a dimension.

HPA

Brimelow and Vasey (1958), in a British patent, described the chemical synthesis of a new class of sulphonamides which held promise as anticonvulsants and diuretics. Walpole (personal communication) and Paget (1958) observed hyperplasia of urinary tract epithelium in rats fed relatively large amounts

HPA
4-Ethylsulphonylnaphthalene-1-sulphonamide

SADA
2-p-Methoxybenzenesulphonamido-5-isobutyl-1,3,4-thiadiazole

of one of these compounds, 4-ethylsulphonylnaphthalene-1-sulphonamide, or HPA (see Formula). The incorporation of as little as 0.01% in the diet of rats—that is, one part in 10,000—induced focal hyperplasia of urinary tract epithelium. For this reason the drug was not introduced for human therapy. This is an excellent example of the piercing scrutiny which is applied during toxicity-testing of new drugs.

My colleagues and I decided that this was an unusual compound, worthy of further investigation, because we knew of no other chemical which had been demonstrated to cause hyperplasia of renal tract epithelium on short-term testing. We therefore gave this compound to mice in the diet at a level of 0.01% for up to 65 weeks (Clayson and Bonser, 1965) and obtained five transitional-cell papillomas and 23 carcinomas of the bladder in 73 effective mice, but no tumours in any other organ. This was also unusual as all the other members of the small group of mouse-bladder carcinogens had induced tumours in other organs as well (Table VII).

TABLE VII.—Bladder Tumours Induced by Oral HPA (Mouse)

Dose	Sex	No. Surviving 30–69 Weeks	Papillomas	Carcinomas	
				No.	%
0.01% in diet	M	34	2	5	15
	F	39	3	18	46

Paget and Walpole's observation was thus very astute, as the hyperplastic action of the drug proved to be the first stage in the carcinogenic action. Clayson, Lawson, Santana, and Bonser (1965) have extended this observation in an attempt to devise a short-term test which could be used to pick out compounds carcinogenic to the bladder by means of their hyperplastic action and thus reduce the testing time to six weeks or less.

SADA

This compound was being investigated for use as a hypoglycaemic agent when it was discovered that it caused bladder tumours when given in the diet to rats, and it was therefore discarded. The chemical structure bore no resemblance to that of any other known carcinogen, which emphasizes how impossible it is, at present, to foretell carcinogenic activity from chemical structure (see Formula).

In Table VIII the results of tests in rats by the oral route are shown. This was a large experiment, adequately controlled. No tumours were obtained until one year of experiment had elapsed, and then only when the drug was given at a concentration of 0.6% or over in the diet, which is much more than is needed relatively in the mouse treated with HPA. Again no tumours were observed in organs other than the bladder.

TABLE VIII.—Induction of Bladder Papillomas and Carcinomas by SADA (Rat)

Dose (% in Diet)	No. of Rats at Start		Bladder Tumours				3 Years	
			1 Year		1½ Years			
	M	F	M	F	M	F	M	F
Control 1 ..	20	20					0	0
0.05-0.4 ..	80	80					0	0
Control 2 ..	10	10						
0.6 ..	10	10		0/4		0/5		
0.8 ..	10	10		1/5		1/5		
				2/4		1/4		
Control 3 ..	20	20						
0.8 ..	30	30			0/15	0/15		
					9/22	4/22		

Although we have no information about the way in which HPA and SADA would act in the human being, no one would dream of permitting their clinical use, because of the extreme potency in man of several other known experimental bladder carcinogens.

Discussion

I have brought to your attention some known or suspected carcinogenic properties of certain therapeutic agents in use or discarded before use in the human being. A more complete list may be found in Roe's (1966) paper.

We are now in a position to discuss the more philosophical problems raised by the facts that I have described to you.

We would all agree that therapeutic compounds which have been proved to induce tumours in man should not be administered for any but the most exceptional clinical purposes—for example, where the expectation of life is short and no other suitable drug is available. It might be suggested also that if a drug is still in the trial stage and is found to be carcinogenic to animals it should be withheld from human use. If we adopt this policy we shall have to realize that we may be withholding a drug which would be of inestimable value in the treatment of a disease or a group of diseases. But what attitude are we to take in regard to a drug which has already proved its worth in the treatment of human disease and has subsequently been shown to cause tumours in animals? The examples I would quote are iron-dextran and isoniazid. In the former case we know that one factor in the development of the experimental tumours is the local accumulation of iron at the site of injection. Therefore I should reserve the use of iron-dextran for patients in the older age groups who do not require large doses continuously or for the acute emergency. I consider that its routine use in pregnant women is unjustified. To vary the injection site might be useful. In regard to isoniazid I should use it as required in the treatment of tuberculosis, though there seems to be recent evidence of bacillary resistance to this compound, but I should not give it prophylactically to young contacts of tuberculous patients, as is the practice in some boroughs in the United Kingdom and elsewhere. It has to be remembered that the duration of the latent period is the most important factor in the quantitative assessment of the causes of cancer and that the longest latent period occurs when exposure starts in childhood.

We now come to the problem of whether all new drugs should be tested for carcinogenic activity before they are marketed. If it were possible to predict this property from chemical structure then such tedious biological work would be avoided. Only occasionally can carcinogenicity be predicted from chemical structure (as I think could now be done in the case of chlor-naphazin). No one could have predicted that HPA and SADA would have this property. I suggest that a commonsense view must be taken of this matter. If a drug is to be used only to treat degenerative disease in old age there is less need for testing than if it is to be used for chronic disease in the young. Any new compound should be tested if a related compound (whether near or distant) is known to be carcinogenic. The strongest argument against testing all new compounds is that it is an expensive task which consumes much skilled scientific labour that could be put to more constructive use, such as the synthesis and preliminary trials of new compounds.

As carcinogenesis is dependent upon the interaction between chemicals and enzyme systems, it is not surprising that species and even strains within a species react in different ways. For example, when the industrial carcinogen 2-naphthylamine is administered to man and the dog, tumours occur in the bladder (and nowhere else), but when administered to the mouse the tumours are in the liver, and in the rat no tumours occur at all. Thus if, on testing a compound in the experimental animal, tumours are induced in the liver, it may be necessary to look for them in the exposed human being in the intestine or bladder. If it happens that the site of election is an organ, such as the intestine, where so-called spontaneous tumours are frequent, any association between the drug and subsequent cancer will not be evident and will require diligent search to uncover it. Linked to this aspect is the gap between the discoveries of the experimentalist and the appreciation by the

clinician of the significance to him and his patient of what has been discovered in the laboratory. Means must be found to bridge this gap.

Summary

The synthesis and exploitation of new therapeutic agents bring hazards as well as benefits to the patient. One hazard is actual or potential carcinogenic action. It is often not realized that the chemical structure of a compound rarely allows prediction of its carcinogenic properties, though it is to be hoped that such a relation will eventually be discovered. At present the only method of demonstrating carcinogenic activity is by laborious tests in animals, and even then the relevance of the results to man is uncertain.

The latent period of tumour induction is long, ranging in the human being from 5 to 40 years. There is no need for the carcinogen to be present during the whole of the latent period, so that a limited exposure in childhood may declare itself later in adult life. Little is known about the relation between the dose and tumour induction.

Carcinogenic therapeutic agents are here discussed as: (1) those of which the cancer-inducing properties were first demonstrated in man; (2) those of which the carcinogenic activity was first seen in animals but the compound had already been given to man; and (3) those which were withheld from man because their tumour-producing potential was discovered by animal experiment.

It is emphasized that laborious statistical investigation may be needed to uncover a relation between therapy and subsequent tumour induction, the treatment of ankylosing spondylitis by x-irradiation being cited as an example.

I hold the view that compounds which have been proved to induce tumours in man should not be administered to patients for any but the most exceptional clinical needs—for example, where the expectation of life is short and no other suitable drug is available. Drugs shown in the trial stage to be carcinogenic in animals should normally be withheld from man, in the knowledge that thereby valuable therapeutic agents may be lost. Drugs which have already proved their worth in therapy and which have subsequently been shown to induce tumours in

animals should be regarded with much suspicion and should in general be withheld from the young and from use as prophylactics. Thus an assessment must be made of the risks and of the benefits in each individual patient. This will be greatly helped by improved communication between the laboratory worker and the clinician.

Six Cases of Acrylamide Poisoning

T. O. GARLAND,* M.D., D.P.H.; M. W. H. PATTERSON,* M.B., CH.B., B.SC.

Brit. med. J., 1967, **4**, 134-138

Early in February 1967 a 19-year-old youth (Case 1) was admitted to the Central Middlesex Hospital with severe peripheral neuropathy and dermatitis of the hands. The occupational health unit was asked to report on any toxic material that he might have contacted at work.

A director of the small factory where he was employed said that they had carefully reviewed all the materials he had handled and none of them could have poisoned him. He was held to be a rather dull lad, who virtually did only labouring work. He lodged with a local farmer, was a poor time-keeper, and by way of recreation spent much time in a local dance hall, which was under suspicion as a place where drugs were peddled.

In appearance the patient bore out this story. His ataxic walk and tendency to fall over almost emphasized it. His

mother had died when he was a child, and life had not been easy for him. He agreed that he was a bad time-keeper, especially lately. However, he denied that he had ever taken drugs, though he had been offered them at the dance hall, and added that lately he had given up smoking and drinking. He knew that he had been working with acrylamide, some of which came from the Cyanamid Co. of New Jersey, and some from Japan, and he told us that the bags from the U.S.A. had a warning label on them.

A further call was made to the factory chemist. He thought that acrylamide could be toxic and remembered having read in a booklet, issued by Cyanamid International, that it poisoned small mammals. The London headquarters of the Cyanamid Co. produced a paper on the toxicology of acrylamide by D. D. McCollister, F. Oyen, and V. K. Rowe, but assured us emphatically that they had no knowledge of any humans having suffered from it. McCollister's description of poisoned

* Central Middlesex Hospital, London N.W.10.

monkeys, however, made us feel fairly sure that the youth had been similarly poisoned.

The managing directors of two other firms making flocculators from acrylamide gave us names of employees whom they thought might have been further cases, and we visited seven factories where acrylamide was used. The cases described occurred in three of the four making flocculators.

A flocculator aids the separation of suspended solids from aqueous systems, which may be useful in mining, soil stabilization, the disposal of industrial wastes, and on any filtration or centrifugal process. There is a use for smaller quantities of acrylamide in the dyeing, photographic, plastic, paper, textile, ceramic, and paint industries.

Acrylamide

Acrylamide ($\text{CH}_2=\text{CHCONH}_2$), a white crystalline powder, is a vinyl monomer which exhibits the usual reactions of the amide group and will readily undergo polymerization and copolymerization. The polymer is non-toxic. It is when handling the monomer or during the process of polymerization that there is a hazard.

It should be noted, in passing, that a small paragraph in the Cyanamid booklet on the chemistry of acrylamide states: "Solutions of acrylamide can be stabilized when necessary by incorporation of cupric and ferrous salts or by organic inhibitors such as hydroquinone and *N*-phenyl- β -naphthylamine." This is a pointer to further care needed if these organic inhibitors are used.

Manufacturing a Flocculator.—The bare outline of the process is as follows: The bags of acrylamide powder are slit along the top with a knife and then emptied manually into a reactor vessel, either through the wide-open top or through a hopper. A catalyst, water, and other chemicals are added. As polymerization proceeds the mixture thickens, finally coming to the state of a gelatinous solid. At this point it is decanted into other vessels and subsequently washed and dried, cut up, and ground. When the polymer is ground up considerable fine dust is produced, but the heavier crystalline monomer does not appear to fly and cause a serious dust hazard. The finished product, sold as a flocculator, is in the form of a granulated solid.

Case Notes

We present these cases under some difficulties. Only one of them has been a patient in this hospital; the others live and work far from London. We have heard of them only through the assistance of their employers, and in regard to their clinical details have been helped by a number of doctors. We have ourselves examined all but one, Case 3, who was away on the Continent. Two are back at work quite well; two have returned—one with serious and the other with mild residual signs and symptoms; one we found still at work though severely poisoned; and one is still off work after eight months.

The situation clearly calls for a great deal more study and trailing, but the wide and growing use of acrylamide justifies an early warning of its dangers.

Case 1. Factory A

A 19-year-old labourer in a very small plant making flocculators first handled acrylamide in December 1966. He was seen in February 1967 complaining of severe muscular aching in the calves and buttocks and with a story of becoming increasingly unsteady on his legs. There was a weakness of his hands, noticed when controlling a bicycle, and finally his legs gave way abruptly on several occasions. The climax arrived in a dance hall, when, having collapsed on the floor, he could not get up again and an ambulance was called for.

The first sign he noticed was in January 1967, when his hands became excessively moist and the skin peeled off, about four weeks after the first contact with acrylamide. Shortly afterwards he was excessively tired and difficult to arouse in the morning, and then the presenting symptoms of weakness and loss of balance appeared. He had lost 7 lb. (3.2 kg.) since December 1966, but had had no diarrhoea.

On examination his palms were moist and peeling. He had a generalized coarse tremor, which had troubled him on two or three occasions in the previous few days. There was also a noticeable slurring of speech.

Neurological examination revealed normal cranial nerves, sluggish reflexes in the arms, and loss of knee and ankle jerks with absent plantar responses. Weakness and wasting of the small muscles of the hands was obvious, together with weakness of the wrist extensors (3/5 M.R.C. scale). Weakness of the dorsi and plantar flexors of the ankles was pronounced. Vibration sense was lost at the wrist and ankle, but there was no other sensory loss, and position sense was not impaired. There was marked truncal ataxia and a positive Romberg sign. C.S.F.: protein 40 mg./100 ml., 4 lymphocytes.

While in hospital his hands healed but the tendon reflexes in the arms disappeared. Otherwise there was little change in his condition, and he was discharged on 9 March.

On 29 April, three months after stopping work, he was still severely disabled and had lost a further 5 lb. (2.3 kg.). He had experienced further episodes of generalized uncontrollable shaking, worse in the upper half of the body. He had no diarrhoea or urinary symptoms. There was muscle-wasting, most pronounced in the anterior tibial compartment, and no return of power, but vibration sense was now intact. Tendon reflexes were absent and Romberg's sign was positive. By June he was much better, but still severely ataxic.

Case 2. Factory B

This man, aged 23, had been working with acrylamide for three months before the skin of his hands peeled. Two weeks later his finger-tips became numb and this numbness gradually crept up his hands. His grip became weak, he found shaving difficult, and he could not appreciate the temperature of his baby's bottle. Six weeks after the onset of symptoms his toes also became numb and his legs progressively weaker, until it became difficult to climb stairs and impossible to run. He stumbled frequently. He had no difficulty with his speech, no tingling, no impotence, no disturbance of micturition, no loss of appetite, and no disturbance of sleep. He worked until admission to hospital three months after his symptoms began.

On admission to hospital on 8 September 1965 there was an absence of tendon reflexes in arms and legs, loss of power in the small muscles of hands and feet, and anaesthesia of the fingers and toes to light touch and pinprick. Vibration sense was intact. C.S.F.: protein 29 mg./100 ml., cells nil.

He was discharged from hospital on 21 September and returned to work at the beginning of November, though there was still weakness of certain hand muscles. By March 1966 tendon reflexes had reappeared, and when we examined him on 17 April 1967, after he had been back working with acrylamide for some months, we found no abnormality whatever.

Case 3. Factory B

This man, aged 30, had been closely concerned with the previous patient (Case 2) developing the process for manufacturing flocculators. He knew his colleague's story and had had similar symptoms, but seems to have put up with them for four or five months before he consulted a neurologist on 10 March 1966.

He felt unbalanced at times when dancing, he had lost his sense of touch, and tended to drop cigarettes. These symptoms were more noticeable after taking alcohol. Generally he was very tired. The neurologist found arm and ankle jerks to be absent. Knee jerks were present though sluggish. There was slight loss of vibration and joint sense in the toes but no other sensory loss. The neurologist had also seen Case 2 and found the present patient much less seriously affected. Recovery was fairly quick and uneventful.

months. With regard to the more severely poisoned, we are still in doubt whether complete recovery ever takes place.

It is a relatively easy hazard to contain. Awareness of the severely toxic nature of the substance on the part of the management and workers is the principal factor in prevention of acrylamide poisoning.

We wish first to thank the managements of the seven factories who allowed us to study their methods of using acrylamide. In particular we are grateful to those directors of factories making flocculators who unearthed cases among their own staff. They could so easily have behaved very much less helpfully.

We thank Dr. J. C. Phemister for his permission to publish Case 1 and for his advice throughout on the neurological aspects. We

thank also the following doctors for answering our letters promptly and giving every assistance they could to our understanding: C. L. Davidson, P. Knight, B. O. Porchetta, J. A. Price, J. V. Reuben, L. W. Smith, and T. Thorburn.

Fructose Intolerance

J. A. BLACK,* M.D., F.R.C.P.; K. SIMPSON,† M.D., M.R.C.P.

Brit. med. J., 1967, 4, 138-141

Fructose intolerance is a genetically determined disorder in which the giving of fructose or fructose-containing sugars such as sucrose causes severe hypoglycaemia, while the continued absorption of small amounts of fructose results in fatty infiltration and fibrosis of the liver. The condition was first described by Chambers and Pratt (1956), and Froesch *et al.* (1957) in Zürich demonstrated the biochemical response in affected individuals to a dose of fructose or sucrose. Since then more than 40 cases have been described, and it is probable that fructose intolerance is at least as common as is galactose intolerance. In all except one family (Wolf *et al.*, 1959) the condition seems to have been inherited as an autosomal recessive.

This is a potentially fatal condition in infancy if untreated; in those infants who survive, hypoglycaemic symptoms may continue throughout childhood and even into adult life, and it is therefore equally important that the family doctor, the paediatrician, and the general physician should be aware of this easily treated disorder.

Case 1

The patient, a girl born on 19 March 1962, was the fourth child of healthy unrelated parents; birth weight 6 lb. 8 oz. (2.95 kg.). She was breast-fed for three days and later fed on various dried milks with the conventional additions of sucrose. On return home from the maternity hospital she began to vomit, lost weight, and became jaundiced. At the age of 1 month she was admitted to hospital. She was a pale, jaundiced baby with a blotchy face and a blood-stained nasal discharge. The abdomen was distended by ascites and by a moderately enlarged liver (two fingerbreadths below the costal margin).

Investigations.—Haemoglobin 8.8 g./100 ml. (61%); W.B.C. 27,000/cu. mm. (neutrophils 71%). Serum bilirubin 5.5 mg./100 ml. Serum alkaline phosphatase 22 units/100 ml.; thymol turbidity 1 unit; S.G.O.T. 140 units/100 ml.; S.G.P.T. 100 units/100 ml. Serum proteins 3.5%, with a lowering of albumin and β -globulin, and an elevated α_1 - and γ -globulin. Urine normal to routine examination.

One week after admission a laparotomy was done (Mr. H. H. Nixon). There was much ascitic fluid and the liver was greenish brown with a finely granular appearance. A piece of liver was removed; part of this was sent for routine histological examination and the rest was kept in a deep freeze. The histological report on the liver (Dr. Barbara Ockenden) was as follows: "There is intra-

lobular bile retention in the canaliculi, with widespread but patchy giant-cell transformation. There is a variable degree of sublobular cirrhosis. A little glycogen is present but there is no fatty change." A provisional diagnosis of giant-cell hepatitis was made, though galactosaemia was also considered, but was excluded by finding a normal activity of galactose-1-phosphate uridyl transferase in the infant's red cells.

After the laparotomy she improved. The urine at this time showed a gross amino-aciduria on two occasions with small quantities of galactose (50 and 12 mg./100 ml.) and traces (less than 5 mg./100 ml.) of glucose, sucrose, fructose, and lactose.

She was discharged at the age of 7 weeks weighing 8 lb. 5 oz. (3.77 kg.) but improvement was not maintained. At the age of 6 months she began to gain weight; by 8 months she weighed 14 lb. 10 oz. (6.63 kg.) and her liver was almost normal in size. Since her progress seemed much better than would have been expected of a child with a severe hepatitis the history was reviewed with her mother, who said that the baby had begun to thrive as soon as she had substituted glucose for sucrose in the feeds. She had done this because she had noticed that the patient's reaction to sucrose was similar to that of her first child (Case 2), whose history follows.

Case 2

This male child born on 26 September 1953 was breast-fed for one month and then changed to dried milk with the usual additions of sucrose. He did not take his feeds well and failed to gain weight on three different milks. A health visitor suggested that it was the sucrose which was upsetting him and advised the mother to use glucose. After this he gained weight but later developed a "screaming dislike" of sweet things, also carrots, peas, baked beans, fruit, and a variety of other foods.

A diagnosis of fructose intolerance in both children now seemed probable, and an oral fructose-tolerance test was performed by Dr. K. Simpson at Leicester Royal Infirmary (they had moved shortly after the diagnosis was suggested in London).

Comment

Case 1 was given 5 g. of fructose (0.5 g./kg. body weight). She vomited soon after her test dose and was sleepy for the rest of the day. A urine specimen during the test contained fructose. The response to the fructose was characteristic of fructose intolerance (Fig. 1). Case 2 was given 13 g. of fructose (0.5 g./kg. body weight). He became pale and drowsy and felt sick. The chemical changes in his blood were also typical of fructose intolerance.

* Consultant Paediatrician, Sheffield Children's Hospital.

† Consultant Paediatrician, Leicester Area.

A fructose-free diet was therefore prepared and the sheet was shown to the mother, but she reported that it contained little information which she and her family had not already worked out for themselves. At the time of writing both children were well and were growing normally. At the age of 3 years 11 months Case 1 weighed 35 lb. (15.9 kg.) and her height was 3 ft. 2 in. (96.5 cm.), while Case 2, aged 12 years 5 months, weighed 88 lb. (40 kg.) and was 4 ft. 11½ in. (152 cm.) tall.

FIG. 1.—Case 1. Aged 1 year. Oral fructose tolerance test; 5 g. of fructose was given by mouth.

Subsequently the piece of liver from the biopsy preserved in the deep freeze at -35°C . was examined by Dr. A. D. Patrick in the Department of Chemical Pathology at the Hospital for Sick Children, London. Aldolase activities, with both fructose-1-phosphate and fructose-1-6-diphosphate as substrates, were estimated by the method of Leuthardt and Wolf (1955). The results (see Table) demonstrated a 50% reduction in the diphosphate aldolase activity and an almost complete absence of fructose-1-phosphate aldolase activity, giving a ratio of 6:1 instead of the normal ratio of approximately 1:1. Some of the same material was also examined by histochemical methods (Lake, 1965) and showed a reduction of aldolase activities with both fructose-1-phosphate and fructose diphosphate as substrates.

Aldolase Activity of Liver

		Activity ($\mu\text{moles NADH/min./g. Wet Wt. of Liver}$)		Activity Ratio F-1-6-P./F-1-P.
		F-1-P. Aldolase	F-1-6-P. Aldolase	
*Control 1	..	0.90	1.00	1.1
*Control 2	..	0.92	0.83	0.9
Case 1	..	0.08	0.49	6.1

* Control specimens were stored under the same conditions and for the same period as the specimen from Case 1.

Case 3

This male child born on 16 March 1964, birth weight 6 lb. 11 oz. (3.04 kg.), was the second child, both parents being healthy and unrelated. He was breast-fed for two days; the feed was then changed to a dried milk with added sucrose. He started vomiting, and at the age of 7 weeks was admitted to the Children's Hospital, Sheffield, with a provisional diagnosis of pyloric stenosis. He weighed 7 lb. 1½ oz. (3.22 kg.) and looked wasted but not dehydrated; there was no evidence of pyloric stenosis. His urine was normal to routine testing. During the next month he continued to feed poorly and did not gain weight: at the age of 11 weeks his liver was enlarged to two fingerbreadths below the costal margin, and in the next two months it increased in size. His urine contained an unidentified reducing substance on one occasion. He was very ill, and it was decided to give him a fructose-free diet without any preliminary tolerance tests. On this diet there was a steady improvement, interrupted only by a further fall in weight when sucrose was added to his feeds in error. During this setback fructose was identified in his urine and the total reducing substances in his blood were 77 mg./100 ml. with 45 mg./100 ml. of glucose:

a considerable proportion of the large difference of 32 mg./100 ml. was thought to represent fructose (a specific method for fructose was not at this time available at the hospital). He finally returned home at the age of 6 months and has been gaining weight steadily (Fig. 2). His liver was normal in size.

FIG. 2.—Case 3. Weight chart showing the effect of the introduction of a fructose-free diet.

The diagnosis in this child was initially obscured by the fact that his elder sister (Case 4) was diagnosed at the age of 5 years as having glycogen storage disease and had had a liver biopsy at the age of 5 years. However, examination of her notes and the biopsy sections showed no real evidence of glycogen storage. Her history follows.

Case 4

The elder sister of Case 3, born 24 May 1953, birth weight 6 lb. 11 oz. (3.04 kg.), was breast-fed for four weeks, then changed to a dried milk with added sucrose. At the age of 7 weeks she was admitted to the City General Hospital, Sheffield, with vomiting thought to be due to pyloric stenosis, but this was not confirmed. At 3 months she weighed 8 lb. 4 oz. (3.74 kg.) and her liver was three fingerbreadths below the costal margin. Her urine contained fructose on one occasion and a reducing substance, "not glucose," on another occasion. She was thought to have glycogen storage disease. At the age of 5 years a liver biopsy showed very marked fatty change, with a normal amount of glycogen. When the diagnosis of fructose intolerance was suggested in her younger brother the evidence for the diagnosis of glycogen storage disease was reviewed. On further questioning the mother said that the child had always avoided sweet things. She was then given a similar diet to that of her brother. It has not been possible to carry out any formal confirmation of the diagnosis in these children.

Case 5

A girl born on 30 September 1957, birth weight 7 lb. (3.18 kg.), was the first child of healthy unrelated parents. She was breast-fed for a few days and then changed to a dried milk. Her mother found that the addition of sucrose to the feeds upset her and therefore stopped adding it. She had always been noticed to have an aversion to sweet things. At the age of 7 years 4 months she attended the Children's Hospital, Sheffield, with a history of listlessness for a few weeks. Since she had started school dinners, which she disliked, she had been generally unwell.

She was a healthy-looking girl, of normal height and weight for her age; the only abnormality was a firm liver enlarged to two fingerbreadths below the costal margin. The urine was normal and contained no reducing substance. It was decided to do an oral fructose-tolerance test. On 12 February 1965 she was given 12.5 g. of fructose (0.5 g./kg. body weight). After one hour she felt faint and looked pale. The level of fructose rose slowly to a maximum of 24 mg./100 ml. at one and a half hours and the blood inorganic phosphorus also fell: the blood glucose level fell sharply from a fasting level of 79 mg. to 30 mg./100 ml. at one hour and 27 mg. at two hours. These results were regarded as typical of fructose intolerance. She seemed well shortly after the test was completed and was allowed to go home. One week later she refused food and two days later complained of abdominal pain: 12 days after the test she was slightly jaundiced and her liver was four fingerbreadths below the costal margin. The urine contained bilirubin and a

slight excess of urobilin, but no fructose. Serum transaminases were raised (S.G.P.T. 920 units/100 ml., S.G.O.T. 480 units/100 ml.), but other liver-function tests were normal. After this she improved slowly on a fructose-free diet, and one month later her liver was two fingerbreadths below the costal margin and transaminases were normal.

Two years after the diagnosis was made she was no longer listless, her liver was just palpable and felt normal. Her teeth had been examined by Mr. R. C. W. Dinsdale, at the Charles Clifford Dental Hospital, Sheffield, and been found to be completely free of caries.

Presentation

The presenting symptoms of fructose intolerance are extremely varied. An infant with this condition will thrive normally as long as he is wholly breast-fed: as soon as feeds containing sucrose—that is, cane sugar or beet sugar—are given, vomiting occurs or the infant may refuse to feed after sucking for a few minutes. Severe neonatal jaundice with hepatomegaly may develop, with signs of acute liver failure, just as may occur in galactose intolerance; or the vomiting may be so severe as to suggest pyloric stenosis. The condition may be fatal in infancy (Sacrez *et al.*, 1962; Levin and Snodgrass, 1965) unless the diagnosis is made promptly or the mother realizes, having had previously affected children, that glucose must be substituted for sucrose. Later the hepatomegaly may suggest glycogen storage disease. By the time school age is reached the child will have learned to exclude sweet things and root vegetables from his diet, but the necessity of eating school meals causes severe distress, which may be interpreted as a behaviour disorder or school phobia. In hypoglycaemic fits, particularly with hepatomegaly, fructose intolerance should always be considered (Levin and Snodgrass, 1965). Swales and Smith (1966) have reported fructose intolerance in an adult and have pointed out that the vague symptoms may often lead to a diagnosis of "neurotic ill-health."

Diagnosis

In many cases of fructose intolerance a detailed dietetic history may point to the correct diagnosis, and it is important not only that artificial milks and infant foods should be accurately labelled, showing the exact monosaccharide or disaccharide which they contain, but also that the physician should know what sugars are added to the feeds of the infant under his care.

It must be emphasized that the absence of fructose in the urine does not exclude fructose intolerance. Even if present, fructosuria will be missed if a glucose-specific (glucose-oxidase) method is used for screening urines. In fructose intolerance, glucose and other sugars may be present in the urine at the same time as fructose, and therefore in any suspected metabolic disorder it should never be assumed that glucose if present is solely responsible for a positive reducing reaction. Chromatography of the urine should be used to identify all the sugars present.

The symptoms in fructose intolerance are due predominantly to the severe hypoglycaemia which occurs after a dose of fructose; nausea, vomiting, and epigastric discomfort are common if the fructose is given orally. The diagnosis can be confirmed by a fructose-tolerance test or by estimating the activity of fructose-1-phosphate aldolase in fresh or frozen liver tissue obtained by biopsy. Fructose-tolerance tests can be performed after an oral dose (0.5 g./kg.), but it has been shown that more satisfactory results can be obtained by an intravenous injection of half the oral dose (Cornblath *et al.*, 1963). Characteristically the fructose level in the blood rises to or above 20 mg./100 ml.; the blood inorganic phosphorus falls, and this is followed by a rapid fall of blood glucose to a level at which symptoms or even fits or unconsciousness may occur; such

severe hypoglycaemia can be rapidly reversed by an intravenous injection of glucose, which should be immediately available during the test. Another disadvantage of the fructose-tolerance test is the delayed development of liver damage, as occurred in our Case 5.

In view of these disadvantages of the tolerance test it is not surprising that a liver biopsy should be thought to be preferable. Our experience confirms what has previously been shown (Sacrez *et al.*, 1962; Desbuquois, 1965), that orthodox histological examination of the liver may be extremely misleading, as the sections may show a "neonatal hepatitis" (Case 1), gross fatty change (Case 4), or early cirrhosis, and it would appear that there are no histological changes which are specific to fructose intolerance. Therefore the only useful investigation on biopsy material is an estimation of the fructose-1-phosphate aldolase activity in the liver.

In practice the ratio of liver aldolase activities with both fructose-1-6-diphosphate and fructose-1-phosphate as substrates is usually determined. This ratio (F.1-6-P./F.1-P.), which is approximately 1 for normal liver, increases to 6 or greater in fructose intolerance due to the almost complete absence of fructose-1-phosphate aldolase activity (Schapira *et al.*, 1961-2). The appreciable activity of fructose-1-phosphate aldolase on fructose diphosphate would account for the moderate decrease in aldolase activity which is observed with the diphosphate as substrate. A liver biopsy may well be the investigation of choice if adequate biochemical facilities are available, but it cannot be too strongly emphasized that neither a liver biopsy nor a fructose-tolerance test should be done when the patient is severely ill; this applies particularly to the newborn infant. A trial of a fructose-free diet can be easily arranged, and a dramatic improvement (Case 3) may give confirmation of the probable diagnosis without in any way prejudicing the performance of a diagnostic test when the patient's condition has improved.

The evidence that in fructose intolerance there is a considerable reduction of fructose-1-phosphate aldolase activity in the liver is based on numerous reports on biopsy material (Desbuquois, 1965). Confirmation of the expected increase in fructose-1-phosphate in the liver of affected individuals has also been provided by Milhaud (1964) and Rossier *et al.* (1966). Apart from this primary defect (Fig. 3) the accumulation of fructose-1-phosphate in the liver appears to inhibit the activity of fructokinase (Froesch *et al.*, 1959) and of fructose-1-6-diphosphate aldolase (Desbuquois, 1965), causing, respectively, a rise in fructose in the extracellular fluids and the inhibition of gluconeogenesis. There is also a block in the release of glucose from the liver; after a dose of fructose glucagon fails to produce its usual hyperglycaemic effect, though the glucagon effect is restored later (Cornblath *et al.*, 1963). It has been suggested that this interruption of glucose release from the liver is due to a failure of phosphorolytic degradation of glycogen, resulting

FIG. 3.—The metabolic pathways of fructose. (1) Indicates site of the primary block in fructose intolerance. (2) Indicates sites of secondary blocks.

from the depletion of intracellular phosphate after its immobilization as fructose-1-phosphate, though this is still uncertain (Desbuquois, 1965). The severe hypoglycaemia resulting from a dose of fructose appears to be the resultant of a failure of glycogenolysis in the liver, with continued peripheral utilization of glucose by the tissues. The cause of the liver damage itself remains unexplained; it is possible that the intrinsic metabolism of the liver cell is damaged, owing to depletion of cellular adenosine triphosphate (Levin *et al.*, 1963).

Treatment and Prognosis

Treatment consists in the exclusion of sucrose and fructose from the diet, with the addition of ascorbic acid, as the daily intake is otherwise likely to be low. Difficulties often arise in the prescription of medicines or antibiotic syrups, and the patients and their doctors need to be warned specifically about this point.

Severe or fatal liver damage is likely to occur in infancy if the diagnosis is not suspected. As the case histories show, the diagnosis is commonly made by an observant mother if she has already had a similarly affected infant, but the exclusion of fructose-containing substances from the diet by the mother, or later by a self-selected diet, is not usually strict enough to prevent the development of hepatomegaly. It is probable, therefore, though there is as yet no certain evidence of this, that the fatty infiltration of the liver will in due course be followed by cirrhosis. Our own observations suggest that a strict fructose-free diet in children will cause a complete return to normality, though a long follow-up has not yet been possible.

Summary

Fructose intolerance is a genetically determined metabolic disorder inherited as an autosomal recessive. It is probably as common as the more widely recognized galactose intolerance.

In affected individuals fructose given orally or intravenously causes profound hypoglycaemia, with a rise of the level of

fructose in the blood to 20 mg./100 ml. or more. The essential abnormality is an absence of the liver enzyme fructose-1-P. aldolase. The condition may present in infancy as neonatal jaundice with hepatomegaly, or with vomiting and failure to thrive: in older children hypoglycaemic fits may occur or glycogen storage disease may be suspected on account of the enlarged liver. In adults the symptoms are less obvious, and may be dismissed as "neurotic ill-health."

The diagnosis is made by an oral or I.V. fructose tolerance test or by estimation of the activity of the specific aldolase in a fresh or frozen liver biopsy.

Treatment is by the exclusion of fructose and sucrose from the diet.

Five children with this condition are described.

We wish to thank Dr. A. D. Patrick, Department of Chemical Pathology, the Hospital for Sick Children, London, for his help in the investigation of Case 1 and for his advice in the preparation of this paper. We are also grateful to Professor Sir Alan Moncrieff, Dr. R. R. Gordon, and Dr. C. B. M. Warren for allowing us access to their clinical records.

Abnormal Splitting of the Second Heart Sound in Renal Failure

D. G. GIBSON,* M.B., B.CHIR., M.R.C.P.

Brit. med. J., 1967, 4, 141-144

Abnormally wide splitting of the second heart sound due to delay in the pulmonary component is a significant physical sign (Leatham, 1958). Though it is most frequently due to right bundle-branch block or an atrial septal defect, it may also result from any condition causing mechanical prolongation of right ventricular systole, such as pulmonary valve stenosis, or from right ventricular failure due to severe pulmonary hypertension (Shapiro *et al.*, 1965). However, delay in pulmonary valve closure by more than 0.03 second, the value usually taken as the upper limit of normal (McKusick, 1958), has been observed in a number of patients with advanced renal failure in whom none of these conditions was present. Since its recognition has proved to be of value in the management of such patients, it is documented here, and its clinical associations are defined more precisely.

Material and Methods

Observations were made during the routine management of eight patients with advanced renal failure. All had radio-

logical evidence of perihilar or interstitial pulmonary oedema, and all but one had dyspnoea, orthopnoea, and crepitations over the lungs. Further clinical, biochemical, and haemodynamic data are summarized in Table I. The haemodynamic data form part of those presented in a previous communication (Gibson, 1966). Biochemical estimations were performed by autoanalyser techniques. The total fluid loss during peritoneal dialysis was calculated from the cumulative balance of each exchange, and during haemodialysis from the weight loss of the patient. Drug therapy was not altered during the procedure, except in Case 8, where ethanol inhalations, morphine, aminophylline, and pentolinium were given without effect on the pulmonary oedema.

Phonocardiograms were recorded from the position along the left sternal edge where the splitting of the second sound was most obvious clinically. A Mingograf direct writing recorder was used, running at a paper speed of 100 mm. per second. On account of the patients' dyspnoea, it was not always pos-

sible to use an indirect carotid pulse transducer, and in these patients the aortic component of the second sound was identified from an apical phonocardiogram. For the same reason, recordings were made during spontaneous respiration rather than held expiration. The heart sounds were timed from their initial deflections. Specimen phonocardiograms are reproduced in Figs. 1–6.

FIG. 1.—Case 2. Phonocardiogram before treatment, recorded from the left sternal edge (LSE) at high (HF) and medium (MF) frequencies. The pulmonary component of the second sound (P_2) occurs 0.055 second after the aortic (A_2), during spontaneous expiration. In this and the other phonocardiograms, the marker represents time intervals of 0.04 second.

FIG. 2.—Case 2. Phonocardiogram after dialysis.

Cases 1–6 were admitted in pulmonary oedema and were treated with hypertonic peritoneal dialysis. Phonocardiograms were recorded before and after the procedure.

Case 7.—This patient had radiographic evidence of pulmonary oedema though it was not causing symptoms. His anaemia was therefore treated with slow infusion of 1.2 litres of packed cells. This caused the appearance of abnormal splitting of the second heart sound and transient dyspnoea, but there were no other untoward effects. Phonocardiograms were recorded before and after the transfusion.

FIG. 3.—Case 3. Phonocardiogram before treatment, showing separation of the two components of the second sound by 0.06 second in expiration.

FIG. 4.—Case 3.—Phonocardiogram after dialysis.

Case 8.—This patient had radiographic evidence of pulmonary oedema, but no undue dyspnoea or orthopnoea. However, wide splitting of the second heart sound was noted clinically and recorded phonocardiographically (P.C.G. 1 in Table III and Fig. 5). To treat his anaemia a slow transfusion of packed cells was started, but after only 100 ml. had been given he developed a severe attack of acute pulmonary oedema which proved resistant to the usual methods of treatment. Haemodialysis by means of a hypertonic bath was therefore started, and within 45 minutes his symptoms had subsided,

FIG. 5.—Case 8. Phonocardiogram before the initial blood transfusion, taken during spontaneous expiration. The aortic component of the second sound, occurring with the incisura on the carotid pulse recording, precedes the pulmonary component by 0.055 second.

FIG. 6.—Case 8. Phonocardiogram after dialysis.

after the net removal of 500 ml. of fluid. P.C.G. 2 was recorded at this time. When the rate of infusion of the blood was increased so that the net fluid loss dropped to 200 ml. mild symptoms recurred and abnormal splitting of the second sound was again evident (P.C.G. 3), but both resolved on further dehydration. P.C.G. 4 was recorded towards the end of the dialysis.

Results

The phonocardiographic observations are summarized in Table II. Wide splitting of the second heart sound in expiration was recorded at some stage in all the patients. This was due to delay in closure of the pulmonary valve relative to that of the aortic by 0.04 to 0.06 second. There was normal inspiratory augmentation of the A_2 - P_2 interval. In Case 7 abnormal splitting appeared after blood transfusion. The relation between changes in blood volume and abnormal splitting was investigated in more detail in Case 8. In this patient the abnormality was relieved after the removal of plasma ultrafiltrate and recurred after blood transfusion. Details of the total volume of blood administered, the net fluid balance of the patient, and the phonocardiographic data are given in Table III.

Other Factors.—There was no consistent reaction between changes in the blood urea level and the development of abnormal splitting. In Cases 1-6 the blood urea was reduced during peritoneal dialysis, as the abnormality was corrected, while in Case 7 it remained unchanged as delay in pulmonary valve closure was provoked by blood transfusion. In Case 8 it fell throughout the haemodialysis as abnormal splitting was precipitated by blood transfusion and relieved by dehydration. Similarly, the return of the heart sounds to normal could be dissociated from changes in the systemic arterial pressure, or from correction of the anaemia, hyperkalaemia, or metabolic acidosis present initially in some of the patients.

Discussion

In the present series of patients, right bundle-branch block as a cause of the abnormal splitting of the second heart sound could be excluded by the absence of the characteristic E.C.G. pattern. There was no supportive evidence of an atrial septal defect, or other congenital heart disease, and, in any case, normal splitting was observed at some stage in all the patients. In no case was there any clinical evidence of severe pulmonary hypertension causing right ventricular failure, and in four patients it was excluded by direct measurement of the right atrial and pulmonary arterial pressures. There was, however, strong correlation with the degree of hydration of the patients. Abnormal splitting was relieved in all patients in whom it was initially present by dehydration, while in two patients the abnormality developed after the administration of blood. Alwall *et al.* (1953) have stressed that pulmonary oedema in renal failure is also a manifestation of fluid overload, and have demonstrated resolution of the radiographic appearances with dehydra-

tion, even in the presence of a rising blood urea. It was therefore of interest that though abnormal splitting was sought in a large number of patients with renal failure it was found only in the presence of pulmonary oedema: in particular, it was not found in patients with gross peripheral oedema due to the nephrotic syndrome, in the absence of pulmonary oedema.

The mechanism by which fluid overload causes delay in pulmonary valve closure is not clear. Theoretically, it might be due to prolongation of right ventricular activation, isovolumic contraction, or ejection. With a normal E.C.G. it is unlikely that selective prolongation of right ventricular activation occurred. In the absence of mechanical obstruction to right ventricular ejection, pulmonary hypertension, or a left-to-right shunt, prolongation of either right ventricular isovolumic contraction or right ventricular ejection implies impairment of the function of the right ventricle relative to that of the left. This might be due to the effect of some toxic metabolite retained as a result of the renal failure. Though the results in Case 8 suggest that external fluid balance is important, such prolongation of right ventricular systole does not occur in normal subjects after the administration of relatively small volumes of fluid. Alternatively, impairment of right ventricular function may be caused by reflex activity. It has been demonstrated that stimulation of the carotid sinus baroreceptors (Daly and Luck, 1958) and also of efferent fibres in the vagus (Daggett *et al.*, 1966) may lead to a reduction in ventricular contractility. In the abnormal circulatory state present in these patients, such reflex activity might have been present.

Delay in the pulmonary component of the second sound has been recorded in a number of similar clinical situations. Though abnormal splitting appears to be unusual in the presence of pulmonary oedema due to left ventricular failure or mitral stenosis, it has been recorded inconstantly in association with the pulmonary oedema of high altitude (Fred *et al.*, 1962), and also under certain circumstances in cholera (Greenough, 1966). In the former condition, cardiac catheterization has revealed high pulmonary arterial pressures, which would provide a satisfactory explanation of a prolonged right ventricular ejection time. In cholera, acute pulmonary oedema, gallop rhythm, and wide splitting of the second heart sound may be provoked by the administration of excess saline in the presence of an uncorrected metabolic acidosis. Though haemodynamic and phonocardiographic data are not yet available, the clinical picture has features in common with that occurring in renal failure. In severe systemic hypertension the interval between the Q wave on the E.C.G. and aortic valve closure is often longer than that predicted from the pulse rate; yet splitting of the second heart sound is usually normal. It has been pointed out that the concomitant delay in pulmonary valve closure has not been adequately explained (Shah and Slodki, 1964). Since seven out of the eight cases described in

the present series were hypertensive, it is possible that a similar mechanism was involved.

In a study of the second heart sound in 118 cases of ostium secundum atrial septal defect, Aygen and Braunwald (1962) found that the mean A_2-P_2 interval was 0.05 second and that if the inspiratory augmentation of the A_2-P_2 interval was less than 0.01 second then the split might be regarded as "fixed." Thus the abnormality described in the present series of patients is comparable to that seen in the average case of atrial septal defect, and is readily apparent on auscultation. Though its absence does not exclude the presence of fluid overload, its presence appears to be a sign of incipient pulmonary oedema. In such circumstances fluid should be administered with caution, since the transfusion of even small amounts has led to the development of acute pulmonary oedema (as in Case 8) or epileptic fits.

Summary

Abnormally wide splitting of the second heart sound, due to delay in the pulmonary component, is described in eight patients with advanced renal failure. In seven the abnormality was relieved after the removal of extracellular fluid by peritoneal dialysis or haemodialysis, and in two it was provoked by blood transfusion. Though the mechanism of its production is not clear, it appears to be a useful sign of fluid overload in the uraemic patient.

I am grateful to the Department of Chemical Pathology for permission to reproduce the results of biochemical investigations; to Mrs. D. Winter, of the Department of Cardiology, for assistance with the phonocardiography; to Dr. P. R. Fleming for helpful discussion; and to Professor M. D. Milne for constructive criticism of the manuscript and for permission to publish observations made on patients admitted under his care.

Effect of Glucagon on Intravenous Glucose Tolerance

Brit. med. J., 1967, 4, 145-146

The plasma insulin response to intestinally administered glucose is greater than that elicited by the same quantity of glucose given intravenously (McIntyre *et al.*, 1965). McIntyre and his colleagues suggested that the most likely explanation is the release from the intestine of a humoral factor which stimulates insulin secretion. The identity of this hormone remains speculative, but the intestinal hormones secretin (Pfeiffer *et al.*, 1965; Dupré *et al.*, 1966; Unger *et al.*, 1966b), pancreozymin (Ketterer *et al.*, 1966), and glucagon (Samols *et al.*, 1965a, 1965b) have all been reported to stimulate the release of insulin.

Glucagon is an attractive possibility. Its presence in the gastrointestinal tract has been indicated by biological (Kenny and Say, 1962; Makman and Sutherland, 1964) and immunochemical techniques (Samols *et al.*, 1966; Unger *et al.*, 1966a). Samols *et al.* (1965a) demonstrated that the injection of 1 mg. of glucagon into normal fasting humans produced a rise in plasma insulin that could not be accounted for by elevation of blood glucose. In addition, glucagon has been shown to stimulate the release of insulin from isolated pancreatic tissue (Candela *et al.*, 1963; Turner and McIntyre, 1966). Furthermore, a rise in plasma glucagon levels was found after the oral administration of 100 g. or more of glucose (Samols *et al.*, 1965b; Lawrence, 1966), though Unger and Eisentraut (1964), Lawrence (1966), and Young and Jenkinson (1966) have observed a fall in plasma glucagon after the ingestion of 50 g. (or 1 g./kg.) of glucose.

McIntyre *et al.* (1965) found that the higher insulin response to intestinal glucose was associated with improved glucose tolerance; arterial blood glucose levels were lower during intestinal infusion than during intravenous infusion of the same quantity of glucose. This effect was also demonstrated in two patients after end-to-side portacaval anastomosis, and could not therefore be accounted for by the removal of ingested glucose from the portal circulation on its initial passage through the liver, as suggested by Scow and Cornfield (1954).

If the intestinal release of glucagon is responsible for the enhanced insulin secretion associated with oral glucose it might also be responsible for the superiority of oral over intravenous glucose tolerance. Such an effect would at first sight seem unlikely, as glucagon administration normally produces glycogenolysis and hyperglycaemia. However, Samols *et al.* (1965a) found that the high plasma insulin levels which resulted from the injection of 1 mg. of glucagon were associated with an increased rate of assimilation of a simultaneously administered rapid intravenous injection of glucose. It seemed possible that a similar effect of glucagon on glucose disposal might be seen with more prolonged infusions of glucose and glucagon, simulating the relatively slow absorption of glucose after oral administration. This possibility was tested in the following studies.

Methods

Eight healthy volunteers were given two separate intravenous infusions of the same quantity of 10% glucose after an overnight fast. On one occasion the glucose was given alone, and on the other glucagon was added to the glucose to give a rate of glucagon infusion of 0.6-12 µg. per minute. The actual quantities given to each subject are shown in the Tables. Glucose was given at a rate of 900 or 600 mg. per minute by means of a constant infusion pump.

Arterial blood was sampled through an indwelling Riley needle. Blood glucose was measured by an automated glucose oxidase method (Cramp, 1967) and plasma insulin by radioimmunoassay (Samols and Bilkus, 1964). Plasma samples were normally stored at -15° C. before insulin assay; those from the glucose-plus-glucagon infusion in Subject 6 were inadvertently left at room temperature and insulin assays were not performed on these samples.

Several subjects experienced nausea at the end of the glucagon infusion. A reaction characteristic of hypoglycaemia was also seen after cessation of the infusion; relief with glucose was rapid.

Results

Plasma insulin results are presented in Table I. In all seven studies in which plasma insulin was measured the levels were higher during the infusion of glucose plus glucagon than with glucose alone. The difference was evident at five minutes and continued to increase during the whole period of sampling. The greatest effect of glucagon on insulin secretion was seen in those subjects who received the largest dose of glucagon. This was particularly striking in Subject 2, in whom the insulin rose very rapidly with the glucagon load and reached a level of 204 µu./ml. at 20 minutes while the equivalent level with glucose alone was only 36 µu./ml.

The blood glucose values are presented in Table II. All subjects showed a more rapid rise in blood glucose during the first 30 minutes of the infusion of glucose plus glucagon than during the first 30 minutes of the infusion of glucose alone, while two of the subjects (Nos. 1 and 6) showed higher levels during the first 90 minutes. In the other six subjects the curves crossed and the blood glucose levels were lower at the end of the glucagon plus glucose infusion. In five of the six subjects the cross-over occurred between 30 and 70 minutes, while in the sixth it did not occur until after 105 minutes.

The magnitude of the difference in glucose levels during the first 30 minutes was, like the insulin response, related to the dose of glucagon administered. In the three subjects (Nos. 6-8) who were given 0.6 or 0.8 µg. of glucagon per minute the blood glucose did not rise more than 17 mg./100 ml. above the corresponding level which resulted when glucose alone was infused. In those subjects who received 2 µg. per minute or more the maximum difference for each individual during the first 30 minutes was not less than 41 mg./100 ml.

Discussion

In these studies glucagon did not produce an early improvement in glucose tolerance, despite the higher plasma insulin levels obtained when glucagon was infused with glucose. Glucose levels were actually higher during the first 30 to 45 minutes of the infusion of glucose plus glucagon than during

the infusion of glucose alone. It would seem that the hyperglycaemic-glycogenolytic effect of glucagon initially overcame the glucose-lowering effect which should have resulted from the increased insulin levels. In four of the subjects there was a change in the shape of the glucose curves during the infusion of glucose plus glucagon; the arterial blood glucose level fell and reached values below those found during the infusion of glucose alone. This suggests that when the short-lived glycogenolytic effect was over the effect of high insulin levels on peripheral glucose uptake could become manifest.

The glycogenolytic effect of glucagon seen in these studies suggests that it is unlikely that glucagon is the intestinal beta-cell stimulant suggested by McIntyre *et al.* (1965). A clear enhancement of insulin secretion can be obtained with 50 g. of oral glucose; elevation of plasma glucagon levels, however, has been consistently demonstrated only with the ingestion of larger doses. In addition, no glycogenolytic effect appears to occur with oral glucose; such an effect was presumably the cause of the higher blood glucose levels which we observed when glucagon was added to an infusion of glucose. Though we made no measurement of plasma glucagon the small amounts of glucagon infused should have produced plasma levels similar to those obtained with oral glucose (Samols *et al.*, 1965b).

Further evidence against the role of intestinal glucagon has been presented by Samols *et al.* (1966). They have claimed that glucagon of intestinal and pancreatic origin can be differentiated immunologically and that the rise in plasma glucagon which occurs after oral glucose is due to pancreatic glucagon. They suggest that stimulation of insulin secretion after oral glucose is enhanced by a high local concentration of glucagon following its release from the alpha cells of the islets of Langerhans. If this hypothesis proves to be correct it will leave unexplained the mechanism by which the signal for enhancement of glucagon, and thus insulin, secretion is trans-

mitted from the intestine after the administration of oral glucose.

Summary

When glucagon and glucose were infused intravenously the rise in plasma insulin was greater than that found when glucose was infused alone. Blood glucose levels were also higher during the first 45 minutes of glucose and glucagon infusion, indicating that under these conditions the blood glucose level was more affected by the glycogenolytic action of glucagon than by the greater insulin release due to glucagon. It is thus unlikely that glucagon-induced elevation of plasma insulin levels is responsible for the superiority of oral over intravenous glucose tolerance.

The Thyroid and Fibrinolysis

N. B. BENNETT,* M.D.; C. M. OGSTON,† M.B.; G. M. McANDREW,‡ M.B., M.R.C.P., M.R.C.P.ED.

Brit. med. J., 1967, 4, 147-148

The profound influence of thyroid dysfunction on metabolic processes is well recognized but only recently has its relation to fibrinolysis been studied. Using a whole blood clot lysis technique, Hume (1965) showed that overall blood fibrinolytic activity is diminished in hyperthyroidism and increased in hypothyroidism; it was suggested that the increased fibrinolytic activity provides a protective mechanism by which the untreated hypothyroid patient is spared the consequences of occlusive vascular disease. We have extended these findings by measuring the individual components of the fibrinolytic enzyme system in patients with hyperthyroidism and hypothyroidism and by observing the changes in the levels of these components during treatment of both disorders.

Methods

Plasminogen Activator.—Euglobulin clot lysis times were estimated by the method of Nilsson and Olow (1962), and the results were expressed by plotting the values logarithmically against units of fibrinolytic activity (Sherry *et al.*, 1959), 10 units being equated arbitrarily with a lysis time of 50 minutes. Such an assessment of plasminogen activator level has been shown to correlate well with specific assays of plasminogen activator (Fletcher *et al.*, 1964).

Plasma Plasminogen.—This was measured by the caseinolytic method of Remmert and Cohen (1949) as modified by Alkjaersig *et al.* (1959). The results were expressed in Sherry units.

Plasma Fibrinogen.—This was estimated by a modification (Ogston and Ogston, 1966) of the method of Ratnoff and Menzie (1951).

Plasma Antiplasmin.—This was assayed by the technique of Sherry *et al.* (1959) with activator-free plasmin prepared by spontaneous activation of plasminogen (Kabi Pharmaceuticals Ltd.) in 50% glycerol. Results were expressed as percentage inhibition of the standard plasmin preparation.

Plasminogen Activation Inhibitor.—This was measured in serum by the method of Bennett (1967). This technique measures an inhibitor of the activation process distinct from antiplasmin.

Subjects

All 18 hyperthyroid patients studied had an elevated four-hour gland uptake of radioactive iodine (range 44–80%, mean

64% of administered dose). All 16 hypothyroid patients showed depressed serum protein-bound iodine levels (range 1–3 µg./100 ml., mean 1.9 µg./100 ml). Patients with infections, inflammatory conditions, or disorders such as renal disease, which are known to alter the fibrinolytic system, were excluded. Inhibitors were not measured in the first 10 subjects studied. The control subjects were age-matched to the thyroid patients, and comprised members of the medical staff, healthy volunteers, and patients convalescent from a number of minor disorders not known to affect fibrinolysis. No formal studies of thyroid function were carried out on these control subjects, but they were clinically euthyroid and free of symptoms or signs of vascular disease.

Results

The mean levels and standard deviations of the components of the fibrinolytic system and fibrinogen are presented in the Table.

Plasminogen Activator Levels.—The mean blood activator level of the hyperthyroid group, 1.7 units, was significantly lower than that of the control subjects, 4.7 units, but the hypothyroid patients had a mean activator level, 5.4 units, only slightly greater than the control group, and the difference was not significant.

Inhibitor of Plasminogen Activation.—Patients in the hypothyroid group had a mean inhibitor level of 1.6 units, which is significantly lower than that of the controls, while the hyperthyroid patients had a mean level of 4.3 units, which is significantly higher than that of the euthyroid subjects. This inhibitor does not appear in the euglobulin fraction, and therefore cannot directly influence activator levels as measured by the euglobulin method.

Plasminogen.—The mean plasma plasminogen level in the hypothyroid group was higher than in the control group, and that in the hyperthyroid group was lower than in the control group. Both differences were significant.

Antiplasmin and Fibrinogen.—In contrast with the other components of the fibrinolytic system, antiplasmin levels did not differ in the three groups. Mean fibrinogen levels were greater in both hyperthyroid and hypothyroid groups than in the control subjects, the elevation in the hyperthyroid patients just reaching the 5% significant level, while the elevation in the hypothyroid subjects did not differ significantly from the controls. The difference between the mean fibrinogen levels of the hyperthyroid and hypothyroid groups themselves was not significant.

Levels of Components of Fibrinolytic Enzyme System and Fibrinogen in Hyperthyroid, Euthyroid, and Hypothyroid Subjects

	Hyperthyroid			Sig. of Diff. between Hyperthyroid and Euthyroid Subjects	Euthyroid			Sig. of Diff. between Hypothyroid and Euthyroid Subjects	Hypothyroid		
	No.	Mean Level	S.D.		No.	Mean Level	S.D.		No.	Mean Level	S.D.
Activator (units)	18	1.7	0.8	P < 0.001	34	4.7	1.9	P > 0.1	16	5.4	1.7
Plasminogen (casein units/ml.)	14	3.58	0.56	P < 0.001	34	4.37	0.38	P < 0.01	14	4.70	0.33
Activation inhibitor (units)	13	4.31	0.98	P < 0.001	34	2.42	0.41	P < 0.001	11	1.58	0.39
Antiplasmin (% inhibition)	13	47.3	2.2	P > 0.1	34	46.4	4.9	P > 0.1	11	45.8	5.2

Serial Studies During Treatment

The serial changes in the components of the fibrinolytic system were measured in one hyperthyroid and one hypothyroid subject during the first six weeks of treatment.

Fig. 1 shows the changes which took place as thyroid overactivity was controlled. Activator levels rose progressively while activation inhibitor fell during the six-week period of observation. Plasminogen, after a very slight fall, rose steadily. All these changes represent a return towards normal levels. Fibrinogen, after a moderate fall during the first two-week

FIG. 1

FIG. 1.—Changes in levels of components of the fibrinolytic system in a hyperthyroid subject during treatment with methylthiouracil. FIG. 2.—Changes in levels of components of the fibrinolytic system in a hypothyroid subject during treatment with L-thyroxine.

period, remained unchanged and antiplasmin levels showed no trend.

Fig. 2 shows the changes which occurred during treatment of the hypothyroid patient with L-thyroxine. During the period of study the observed changes were the reverse of those found during the control of thyroid overactivity, levels again returning toward the mean normal values.

Discussion

Altered fibrinolytic activity may be implicated in the formation of intravascular thrombi, and Hume (1965) suggested that the depression of fibrinolytic activity after administration of L-thyroxine might be important in causing acute coronary occlusion in treated hypothyroidism. However, the role of the fibrinolytic system in occlusive vascular disease remains speculative, and it is probable that this system has fundamental functions unrelated to the pathogenesis of coronary artery occlusion. The changes which we have observed in thyroid disorders represent fundamental alterations in the balance of the system. Plasminogen, plasminogen activator, and an inhibitor of activation show changes in opposite directions in hyperthyroid and hypothyroid subjects. In addition, the levels of these factors return to normal as the euthyroid state is restored by treatment with antithyroid drugs or L-thyroxine. The results presented in this study suggest that the fibrinolytic

system is a further metabolic process influenced by thyroid hormones. Further, they suggest that the activity of the normal thyroid gland may influence physiological changes in fibrinolysis, the regulation of which is as yet not understood.

Summary

Hypothyroidism is associated with an increase in plasminogen, a decrease in an inhibitor of plasminogen activation, and a possible increase in plasminogen activator, whereas hyperthyroid

FIG. 2

patients show opposite changes in the blood fibrinolytic enzyme system. These changes may play some part in the association between treated hypothyroidism and occlusive coronary disease. More fundamentally they suggest that the thyroid has a regulating influence on fibrinolysis.

We are grateful to Professor H. W. Fullerton and Dr. T. N. Morgan for permission to study patients in their care, and to Dr. D. Ogston for his advice in the preparation of this paper.

This work was supported by a grant from the Tobacco Research Council on the recommendation of the British Heart Foundation, and was carried out during the tenure of a Medical Research Council Junior Research Fellowship by N. B. B.

Injury, Serum Lipids, Fat Embolism, and Clofibrate

M. O'DRISCOLL,* F.R.C.S.; F. J. POWELL,† M.Sc., A.R.I.C.

Brit. med. J., 1967, 4, 149-151

The mechanism of fat embolism following injury has excited much controversy since it was first described by Zenker in 1862. Two theories seek to explain it—the classical mechanical theory, which is supported by Sevitt (1962), and the metabolic theory, which is supported by Evarts (1965). The mechanical theory suggests that following trauma fat is liberated from the marrow cavity into the venous sinusoids, whence it passes in the form of globules into the systemic circulation. The metabolic theory suggests that tissue injury may initiate changes in the physicochemical state of the blood, and that this alters the emulsion stability of the blood lipids. Together with the activation of a lipid-mobilizing hormone by trauma this results in the formation of fat globules.

Fat embolism follows trauma (usually to bones). There is a lucid interval of variable duration and then signs of respiratory and systemic fat embolism develop, together with changes in the mental state and level of consciousness; a petechial rash also occurs on the head, neck, and thorax.

In this study, firstly, an attempt was made to try to establish whether there was any change in the serum non-cholesterol lipids after trauma; secondly, the incidence of all degrees of the syndrome of fat embolism was investigated; and, thirdly, the effect of Atromid (clofibrate) on the serum lipids and the incidence of fat embolism was studied. Clofibrate was used because it has an effect on the lipids of the hyperlipaemic patient and has also been found to depress postprandial lipaemia.

Material and Methods

The patients were inmates of the orthopaedic unit at St. James's Hospital, Leeds, either as a result of injury serious enough to warrant admission or because they were undergoing orthopaedic surgery. They were divided into two groups (Table I). One group received standard therapy, and the other received clofibrate as well, as soon as they were able to take capsules. The dosage of clofibrate used was 750 mg. by mouth followed by 500 mg. six-hourly for two days, then 250 mg. six-hourly for three days, then 250 mg. twice daily for two days, and finally 250 mg. daily for two days. The dose was tailed off to prevent any rebound effects. Eight patients who had had operations on non-bony structures also received clofibrate.

Laboratory Estimations

Plasma total lipids were estimated by the rapid turbimetric method of Kunkel *et al.* (1948), giving normal ranges between 340 and 640 mg./100 ml. and a 5 % error against standard sera. Cholesterol levels were measured by the method of Carr and Drekter (1956) on the first 30 samples and subsequently by direct estimation on an autoanalyser (Kenny and Jamieson, 1963). Cholesterol levels were then subtracted from the total levels to give the non-cholesterol lipid levels.

Sputum was examined for fat globules by adding scharlach R and then by direct microscopy. Urine (end samples) were examined by centrifugation for five minutes, adding scharlach R to the deposit, and then by direct microscopy. Specimens of

sputum from 10 patients with chronic bronchitis in acute exacerbation and samples of urine from six patients with prostatic hypertrophy and urinary infection were examined as controls.

Blood was drawn from an arm vein, with tourniquet, of all patients on arrival in the casualty department, or immediately preoperatively in patients undergoing orthopaedic operations.

TABLE I.—Patients in the Series and Injuries Sustained

Total	79	46

Further samples were taken on the next five or six days, with the patients fasting. Blood was also drawn from the femoral vein of the injured limb in nine patients with fractures of the leg—before, during, and after manipulation, when the patients were anaesthetized for the manipulation.

Clinical Examination

Features noted were (a) mental and conscious state ; (b) skin and conjunctivae for petechiae ; (c) the results of chest examination, particularly for central rales and other signs of pulmonary oedema (radiography being performed on the slightest evidence of abnormality and the x-ray film being compared with the earlier chest x-ray film) ; (d) neurological examination ; and (e) pulse and respiration rate and any signs of so-called "fracture fever"

Necropsy was carried out on the patients who died.

TABLE II

Major Fat Embolism	Minor Fat Embolism
(a) Post-mortem findings of fat embolism	(a) Fat globules in sputum
(b) Petechial rash	(b) Haemoptysis
(c) Confusional states lapsing into coma	(c) Signs of central pulmonary oedema

	(e) Fat globules found in end samples of urine

* Orthopaedic Registrar, Central Middlesex Hospital, London N.W.10.

† Head Biochemist, St. James's Hospital, Leeds 9.

Though the florid syndrome of fat embolism is easy to diagnose, many subclinical cases occur, with few if any of the classical signs, and may be diagnosed only by chest radiography (Berrigan *et al.*, 1966). We have therefore classified our patients into two groups (Table II).

To make the diagnosis of fat embolism we required one major plus one minor criterion; or three or more minor criteria, of which one had to be the presence of changes in the chest radiograph.

Results

Serum Lipids

Daily estimation of the serum non-cholesterol lipid levels showed minimal or no deviation from the normal on any of the six days after operation in the control group; graphs were plotted of the lipid levels of all the subjects: Fig. 1 shows that in those not receiving clofibrate there was an appreciable rise

FIG. 1

Fig. 1.—Serum lipids of total cases. Fig. 2.—Serum lipids of patients on clofibrate for one procedure and not for another.

FIG. 2

to the third and fourth days, which fell off slowly. In the patients receiving clofibrate, on the other hand, lipid levels did not rise. The difference was statistically significant. Moreover, when the seriously injured patients were considered separately the difference in lipaemia between those receiving clofibrate and those not was even more apparent. This difference was noted again in seven patients, each of whom underwent two operative procedures of comparable severity, one being covered by treatment with clofibrate and the other not (Fig. 2).

Samples of blood were obtained from the femoral vein in nine patients, of whom four had closed fractures of the femoral shaft, three had closed fractures of the tibia and fibula, and two had compound fractures of the tibia and fibula. The samples were taken with wide-bore needles from the vein of the affected limb, high up against the inguinal ligament to catch blood issuing from the profunda femoris vein as well. Three

any stage. Of the total of 125 patients, seven were found to have fat in their urine, and it did not appear until the fourth day.

Of the patients who did not receive clofibrate, 30 had chest signs, usually in the mid-zone, or raised respiratory and pulse rates, or haemoptysis, or combinations of these. Pleuritic pain, usually left-sided, was also noted in eight cases. Of the clofibrate-treated patients three had fat in their sputum, increased respiratory and pulse rate, and rales; one patient also had pleuritic pain. Of the patients with abnormal chest signs and fat in the sputum, 27 had chest x-ray changes compatible with pulmonary oedema. No patients treated with clofibrate had chest x-ray changes.

The presence of a petechial rash was looked for in a good light. It was found in seven patients of the non-clofibrate group (five of whom also had confusion and marked chest x-ray changes). Nevertheless, the rash was not present in one patient who died of fat embolism. None of the clofibrate-treated patients developed a rash.

Coma, which carries a grave prognostic sign in fat embolism, occurred in one patient in the non-clofibrate group after a lucid interval of 24 hours. Four other patients became very confused, requiring sedation for several days, and becoming normal again only after several weeks. Two of these patients had temporary loss of sphincter control.

Six patients died in the non-clofibrate group (three from fat embolism), and none in the clofibrate group.

Stainable fat globules in sputum are thought significant of fat embolism (Robb-Smith, 1941).

TABLE III

Injury	Serum Lipids (mg./100 ml.)			
	Arm Vein	Femoral Vein, Pre-manipulation	Femoral Vein During Manipulation	Femoral Vein, Post-manipulation
Femur fracture (closed)	170	160	120	120
	500	500	500	490
	857	857	744	800
	515	494	494	510

	770	725	720	700
	445	415	410	387
Tibia and fibula fracture (compound)	214	208	195	190
	528	479	429	460

Diagnosis of Fat Embolism

The diagnosis was made by using our system of criteria. In the non-clofibrate group three had fat in the sputum and chest signs, but no x-ray changes, so were not thought to have fat embolism. Twenty-seven other patients had either one or more major signs, or three or more minor signs, with x-ray changes, and hence were thought to have fat embolism.

A careful note was made of the day on which the features of fat embolism were sufficient to warrant diagnosis; from Day 1 to Day 6 the numbers of cases were 2, 7, 13, 4, 1, and 0 respectively. These figures corresponded with the distribution of the maximum serum-lipid concentration (Fig. 3).

FIG. 3.—Comparison of days of onset of fat embolism and days of peak of lipids.

Illustrative Case

A youth aged 19 was involved in a motor-cycle crash. He was not knocked out, but on admission was clinically shocked though fully conscious and alert. He had sustained a compound fracture of the mid-shaft of the right femur, a compound fracture of the right patella penetrating the knee joint, and a compound fracture of his right tibia and fibula. He needed a transfusion of 3 pints (1.7 l.) of blood before he was fit enough for wound toilet, patellectomy, and manipulation of the fractures—which were done under general anaesthesia, the fractures being immobilized on a Thompson splint and using plaster-of-Paris. Postoperatively he remained well for 24 hours, after which he became confused and comatose within three hours. Fat embolism was diagnosed in view of the history of injury; the absence of signs of intercranial haemorrhage, the presence of rales, and a petechial rash on examination; and the appearances suggesting pulmonary oedema on chest x-ray film. He also developed ankle clonus, a raised pulse rate, and a temperature of 100° F. (37.8° C.).

He was treated with intermittent positive-pressure respiration and hypothermia. For five days he made some improvement on this regimen, but deterioration occurred and he died on the sixth day after injury. Necropsy showed gross petechial haemorrhages throughout the brain, particularly in the pons and medulla, and, histologically, intracapillary fat globules were present in the brain and in the lung vessels.

Discussion

Much evidence shows that fat embolism is not entirely due to fat getting into the circulation mechanically. The existence of lipaemia after trauma was demonstrated as long ago as 1921 (Bloor, 1921). Johnson and Svanborg (1956) and Bergentz (1961) have demonstrated this in animals, while Gottlieb (1964) has described this in patients who did not have a fracture.

We have shown that a definite lipaemia exists after injury or operation to bone, which rises to a maximum three to four days later and then falls off fairly rapidly. The degree of lipaemia was found to have no relation to the occurrence of fat embolism, but in those patients who had some degree of fat embolism it was at least double the earliest concentration determined. On the other hand, there was a definite correlation between the peak of the lipaemia and the onset of signs of fat embolism. The incidence of clinically recognizable fat embolism was high in the non-clofibrate group (34.2%), and there were three deaths (3.75%)—a figure which agrees with other series (Sevitt, 1962; Evarts, 1965). In the clofibrate group, on the other hand, there were only two cases (4.3%), and no deaths occurred.

Since clofibrate appears to have diminished both lipaemia and fat embolism, it is logical to suggest that the relation between the last two may be causal. Barrett (quoted by Thorpe, 1962) believes that clofibrate acts by virtue of its affinity for serum albumin, resulting in the reduction of the adrenaline-stimulated release of free fatty acids from the fat stores. This in its turn suggests that adrenaline may be implicated in the pathogenesis of fat embolism. Baur and Ludin (1950) found that irradiation of the spine of patients with ankylosing spondylitis caused a rise in the serum histamine concentration as a result of bone-marrow damage. Histamine is known to mobilize adrenaline, and this further mobilizes fat from fat depots. Since bone marrow is damaged by trauma, this could be a possible sequence leading eventually to fat embolism.

A further point in favour of a metabolic cause for fat embolism is our finding on the femoral vein samples. In none of these samples were we able to demonstrate the presence of a shower of fat; in fact, if anything the fat levels in blood draining from the injured limb were lower than those in concomitantly taken arm vein samples.

Summary

A significant lipaemia was found in 79 patients who were followed for a period of six days after trauma, and corresponded at its peak to the onset of fat embolism. There were 27 patients with some degree of fat embolism, three of whom died. A series of 46 patients with bone injury were treated with clofibrate. Lipaemia was substantially reduced and only two instances of fat embolism occurred.

We would like to thank Mr. R. Broomhead, Mr. J. M. Fitton, and Mr. F. W. Shea, orthopaedic surgeons, St. James's Hospital, Leeds; Dr. J. Goldie and the staff of the pathology department, St. James's Hospital, Leeds; Mr. J. M. O'Mahoney and Mr. D. Macwilliams; Mr. J. G. Bonin and Mr. A. J. Howse, of the orthopaedic unit, the Central Middlesex Hospital, London; and Dr. S. L. Lewis for their help.

Behçet's Syndrome with Aortic Aneurysms

ELIZABETH A. HILLS,* M.B., M.R.C.P.

Brit. med. J., 1967, 4, 152-154

The coexistence of mouth and genital ulceration with hypopyon mentioned by Hippocrates and described by various workers in the early part of this century was first defined as a syndrome by Behçet in 1937. The place of the syndrome as part of a systemic disorder is now clearer, and the underlying pathology appears to be a vasculitis. The disease runs a chronic course, blindness being the greatest disability and central nervous system involvement a cause of death. Thrombophlebitis is fairly frequent, France *et al.* (1951) giving an incidence of 25% and Dowling (1961) 12%; superficial thrombophlebitis migrans and thrombosis of large veins, including venae cavae (Thomas, 1947; Boohkos, 1960) are recorded.

Little attention has been paid to arterial involvement (Schneider, 1965). Mishima *et al.* (1961) described resection of an aortic aneurysm in a 38-year-old man with Behçet's syndrome, and since then have seen a patient with a femoral artery aneurysm (personal communication); Oshima *et al.* (1963) record two aneurysms of smaller arteries; Shikano (1966) mentioned that one of his patients died of a ruptured aortic aneurysm. Mounsey in a clinicopathological conference (*Brit. med. J.*, 1966) described a case of ruptured aortic aneurysm in Behçet's syndrome, treated by aorto-iliac graft: in this case the aortic aneurysm was presumed to be secondary to osteomyelitis of the lumbar spine, though the possible association between aortic aneurysm and Behçet's syndrome was raised.

A further case is reported here, in which arterial aneurysms appeared to form part of this generalized disease.

Case Report

The patient's illness began in 1954, when he was in an Army unit containing men who had been serving in Egypt. He had fever and abdominal pain, appendicectomy was performed, but his symptoms continued for three months. Prolonged pain in the left wrist followed minor trauma, and six months later pains developed in the neck, shoulder, and back, with radiation down the back of the thigh. This was attributed to Scheuermann's disease, and after six months in hospital he was discharged from the Service, wearing a plaster jacket. He began to work in the following year, and was well until 1958. He then had osteomyelitis of the jaw after dental infection. Two weeks later he was admitted to hospital with fever and abdominal pain, followed by fleeting joint pains and a rash resembling erythema nodosum. Intensive investigations did not provide a diagnosis, and he was treated for six weeks with bed rest, aspirin, antibiotics, and corticosteroids, and was discharged well. From this time onwards he had recurrent ulcers of the mouth, penis, and scrotum. In 1960 he had an unexplained venous thrombosis of the left leg, and one year later had a right femoral vein thrombosis. Biopsy of the long saphenous vein showed gross thickening of the vein and infiltration with inflammatory cells, particularly around nutrient vessels (Dr. J. G. Leopold). Because of this, long-term anticoagulant therapy was instituted. In 1962-4 he had episodes of haziness of vision, and in 1964 had bilateral iritis and later a vitreous haemorrhage. He was seen by Mr. Vine Cole, who suggested the diagnosis of Behçet's syndrome, based on the association of aphthous mouth and genital ulceration, panuveitis, and thrombophlebitis. Corticosteroid therapy was begun.

In October 1964 the first recognized pulmonary infarct occurred. Since then he had experienced numerous episodes of febrile pleurisy associated with haemoptysis and transient radiological shadowing. Possibly these are due to thrombosis in pulmonary vessels rather than to embolization. During treatment with steroids and anticoagulants he had a haematemesis and later melaena; anticoagulants were withdrawn. In 1965 right-sided loin pain and haematuria were attributed to renal infarction. In April 1966 he complained of severe continuous pain at the base of the spine and a lesser pain in the shoulders. There was associated severe constipation and rectal bleeding. Barium enema was normal. During five weeks in hospital no cause for the pain was found. After discharge from hospital the pain continued, and in August 1966 became so severe that he was admitted to the Cardiff Royal Infirmary, very ill, Cushingoid in appearance, with a temperature of 37° C., blood pressure 130/80, and dusky, scaling nodules, 0.5-1 cm. in diameter, on both legs. There was some tenderness over the sacroiliac joints but no other arthropathy. He had aphthous ulcers on the lateral border of the tongue and inner surface of the lip. In the right fundus there were many haemorrhages, and central retinal artery thrombosis, and in the left eye less marked vasculitis. Carotid and radial pulses were normal, but the left femoral pulse was weak and the right femoral pulse absent. The abdominal aorta was palpable well to the right of the epigastrium and a bruit could be heard. The abdomen was diffusely tender, and slight movement in bed caused severe lumbar and sacroiliac pain. Psoas spasm was present.

Investigations.—Haemoglobin 12.4 g./100 ml.; white cells 12,200/cu. mm. (polymorphs 55%); platelets 453,000/cu. mm. Plasma fibrinogen 650 mg./100 ml. Total serum proteins 7.5 g./100 ml. (albumin 3.8 g.); electrophoresis showed slight increase in globulin. No L.E. cells present. No evidence of bacterial, mycoplasmal, or viral infection. E.C.G. normal. Chest x-ray film showed heart of normal size; shadowing in the right mid-zone.

FIG. 1.—Thoracic aortogram. Fusiform dilatation of lower portion of aorta.

* Senior Medical Registrar, the Royal Infirmary, Cardiff.

The pain became worse and the abdomen more distended. Pressure over the aorta produced severe pain in the back.

Aortograms (Figs. 1 and 2) (Dr. G. de B. Hinde) showed fusiform dilatation of the thoracic aorta, extending to the level of the renal arteries. Below the renal arteries a segment of aorta appeared narrow, and distal to this a large aneurysm involved the superior

Fig. 2.—Upper abdominal aortogram. Fusiform aortic dilatation extending to level of renal arteries.

mesenteric artery, extending to the level of the inferior mesenteric artery.

At laparotomy Mr. Gordon Heard found the aorta and its branches grossly thickened and inflamed, and only $\frac{3}{4}$ in. (2 cm.) at the level of the renal arteries appeared relatively normal, aneurysmal changes extending above and below. Adjacent lymph nodes were somewhat enlarged. No source of infection could be found. Because the aorta was densely adherent to the posterior abdominal wall resection was not attempted, but a bypass graft was inserted from below the renal arteries to the common iliac arteries. An excised lymph node showed nonspecific reactive hyperplasia.

After operation there was some delay before bowel function was satisfactory, but no other problems. He was maintained on prednisolone, 20 mg. daily, with injections of A.C.T.H. 40 units on alternate days. On smaller doses of corticosteroids his vision deteriorated and mouth ulceration was very painful. He had pain between the shoulder-blades which probably differed from that associated with his episodes of pulmonary infarction. A recent penetrated chest radiograph showed less dilatation of the lower thoracic aorta than was seen in the aortogram.

Discussion

Behçet's disease is not very rare in this country; the patients attend ophthalmological, dermatological, or gynaecological departments or do not seek medical advice. Episodes of unexplained fever and arthralgia are soon forgotten and the manifestations of the disease will be separated by such long intervals that several years elapse before their relation as part of a systemic disorder is recognized. If a young patient has arthritis, fever, and an arteritis, a diagnosis of polyarteritis nodosa or systemic lupus erythematosus is usually made. Oral or genital ulceration is not usually mentioned unless specific inquiry is made for these symptoms, and at this stage uveitis may not be present to help the diagnostician.

In young patients aneurysms may not be suspected, particularly now that syphilis and tuberculosis are less common. Had the possibility of aneurysms in Behçet's disease been recognized an earlier diagnosis might have been made in this case. The diagnosis made in April 1966 was of intestinal obstruction, but investigation showed no mechanical cause and

the condition improved. This transient bowel obstruction was probably due to involvement of the inferior mesenteric artery, and in an elderly man the possibility that this event associated with severe back pain was due to aortic aneurysm would not be overlooked. The severe lumbar pain, which is probably due to inflammatory stretching of the arterial wall, may be confused with pain of spinal origin. Arthropathy, possibly spondylitis, is part of the syndrome; many patients are taking corticosteroid therapy, which may cause vertebral collapse. If there are no radiological changes in the spine and pain is persistent, acute inflammatory disease of the aorta should be considered.

It was suspected that the aneurysm was due to acute infection, perhaps associated with corticosteroid therapy, but careful search failed to reveal source of infection. The macroscopic appearances of the aorta can only be explained by acute inflammatory disease, unlike the granulomatous changes which may be seen in the aorta in Takayasu's disease, associated with distant tuberculosis, or the more chronic destructive lesions seen in tertiary syphilis. Both these latter conditions may be regarded as immune response to infection, in which a delayed sensitivity reaction is found in the aortic wall. In Takayasu's disease antibodies to the aorta are found (Ito, 1966). It is very likely that a search for aortic antibodies in Behçet's disease will give positive results, as antibodies to oral mucosa have been demonstrated (Lehner, 1967), and by immunofluorescent staining of peripheral blood films (Shimizu *et al.*, 1965) less specific cytoplasmic antibodies have been found.

The cytoplasmic antibody was similar to those occurring in polyarteritis nodosa, rheumatoid arthritis, and dermatomyositis, in contrast to the antinuclear factor found in systemic lupus erythematosus. These immunological findings support the clinical impression that Behçet's syndrome is related to the collagen diseases. Aneurysms of the aorta are described in polyarteritis nodosa (Wolff, 1936) and with giant-cell arteritis (Gilmour, 1941; McMillan, 1950); it must be remembered that division of these syndromes is often artificial, and firm rules may not be stated that only large or small arteries are involved in certain diseases. The evidence for viral infection in Behçet's disease (Sezer, 1956; Evans *et al.*, 1957) has not been conclusive, but the histological appearances could be due to such infection.

Until the cause of the disease is known treatment is empirical. The immediate treatment of the aneurysms must be surgical. Corticosteroids appear to suppress troublesome general symptoms of the disease in some patients, but there is no evidence that they halt the basic underlying disease process. Indeed, it is possible that this therapy may have played some part in the pathogenesis of the aneurysms. The other possible measure is immunosuppression with a drug such as azathioprine, but this will rest on less sure ground than its use in systemic lupus erythematosus. Such therapy is still experimental in this condition, in glomerulonephritis, and in rheumatoid arthritis, but might be tried in patients who have Behçet's disease with life-threatening complications.

The possible association of aortic aneurysms with Behçet's syndrome is suggested by an increasing number of reports, mostly of isolated cases, in the world literature. This complication should therefore be borne in mind in the management of Behçet's syndrome.

Summary

A case is described of aortic aneurysms occurring in a patient with a 12-year history of Behçet's disease. Their relation to the disease is discussed. It is suggested that specific symptoms of the syndrome should be sought in young persons with aneurysms. Aneurysm formation, a possibly fatal complication,

should be considered as a possible cause of pain in Behçet's disease. Treatment is discussed.

My thanks are due to Dr. William Phillips for permission to publish this case, and to the staff of other hospitals for their helpful information.

Medical Memoranda

Murmur over Liver in Cases of Severe Anaemia

Brit. med. J., 1967, **4**, 154

A murmur may be audible over the heart and blood vessels in cases of anaemia. A systolic murmur was heard over the liver in three cases of severe anaemia. To our knowledge no reference to such a murmur has been made previously.

CASE REPORTS

The patients were female aged 38, 40, and 12 years suffering from nutritional macrocytic anaemia with ankylostomiasis, nutritional macrocytic anaemia, and thalassaemia. The chief complaints were weakness, pallor, palpitation, exertional dyspnoea, and dependent oedema. Their haemoglobin levels varied from 1.45 to 2.9 g./100 ml. The pulse was of water-hammer type and the rate varied

Phonocardiographic record of murmur over the liver.

between 120 and 130 a minute. The respiratory rate was 20 to 26 a minute. Their blood pressures were 60/0, 115/45, and 110/40 mm. Hg. The neck veins were very distended. The sites of apical impulse were the fifth intercostal space 1 cm. outside the mid-clavicular line, left sixth space 2.5 cm. outside the midclavicular line, and left fifth space on the midclavicular line. One patient had a diastolic gallop. There was no murmur in peripheral vessels. In two patients a soft systolic murmur was heard over the pulmonary area. Their electrocardiograms did not reveal any significant abnormality. The liver was non-pulsatile, tender, and enlarged to 3-4

fingerbreadths below the right costal arch. It was soft in two cases and firm in one. There was a systolic high-pitched murmur over the liver, best heard about 2.5 cm. below the costal arch in the continuation of the right midclavicular line. Application of pressure over the area by the chest-piece of the stethoscope made the murmur a little louder. A phonocardiogram taken in one of the cases recorded the systolic murmur (see Fig.).

In the first case transfusion of 300 ml. of whole blood precipitated pulmonary oedema. Partial exchange transfusion of 400 ml. of concentrated red cells with simultaneous withdrawal of 500 ml. of blood saved her. The other two patients had a very slow transfusion of 200 ml. of concentrated red cells. With transfusion of blood the patients became less dyspnoeic, their pulse rates came down, blood pressures improved, the size of the livers diminished, and the murmurs disappeared within a few hours.

COMMENT

The murmur was probably produced in the hepatic artery owing to accelerated circulation of blood through it as a manifestation of hyperkinetic circulatory state. After appropriate blood transfusion along with improvement of the circulatory state, the size of the liver was reduced and the murmur disappeared.

The murmur was best heard over the liver about 2.5 cm. below the costal arch in the continuation of the right mid-clavicular line. This site suggests that the origin of the murmur was in the hepatic artery. The murmur was not a transmitted one from the heart or the abdominal aorta, as in none of these cases was there a murmur in the abdominal aorta and that heard over the pulmonary area was never very pronounced.

We are grateful to Dr. K. C. Sarbadhikari, Principal-cum-Superintendent, Medical College and Hospitals, Calcutta, for allowing us to publish these cases. Our thanks are due to Dr. R. N. Roy for haematological investigations; to Dr. C. R. Maiti for phonocardiography; and to Dr. P. C. Mitra and Dr. S. B. Dutta, of the Central Blood Bank, Calcutta, for performing partial exchange transfusion.

Carbamazepine-induced Jaundice

Brit. med. J., 1967, 4, 155

Carbamazepine (5-carbamyl-5H-dibenzazepine; Tegretol) has been shown to be effective in the treatment of trigeminal neuralgia (Blom, 1962, 1963; McArdle, 1963; Taylor, 1963; Spillane, 1964; Vanderfield, 1964; Burke, Grant, and Selby, 1965; Campbell, Graham, and Zilkha, 1966). Apart from two fatal cases of aplastic anaemia (Spillane, 1964; Donaldson and Graham, 1965) and one case of Stevens-Johnson syndrome (Coombes, 1965) the other side-effects of the drug have been of a relatively trivial nature, such as transient giddiness, drowsiness, ataxia, diarrhoea, anorexia, and an itching erythematous rash (Blom, 1963; Spillane, 1964; Vanderfield, 1964; Burke *et al.*, 1965; Graham and Zilkha, 1966). Obstructive jaundice occurring on the 20th day of treatment with carbamazepine was described by Spillane (1964), but as the patient had had an antecedent gall bladder dyspepsia for 18 months it could not be conclusively proved that the jaundice was drug induced.

In the following case jaundice was associated with the administration of carbamazepine and recurred after a drug challenge.

CASE REPORT

A man aged 65 was admitted to hospital on 14 January 1965 with a history of several days of severe right-sided trigeminal neuralgia, which he had suffered from intermittently for 15 years. His attacks of pain were not relieved by phenobarbitone 60 mg. eight-hourly and pethidine 100 mg. six-hourly. On 21 January

Graph showing liver-function tests before and after a drug challenge with 100 mg. of carbamazepine (Tegretol) daily.

carbamazepine was started in a dose of 100 mg. b.d., increasing gradually up to 200 mg. q.i.d., by which time his pain had completely disappeared. He was sent home on 11 February.

On 24 February he was readmitted with a history of anorexia for 10 days, dark urine for seven days, epigastric pain for three days, and jaundice for one day. He had no pruritus. He had continued taking carbamazepine in a dosage of 200 mg. q.i.d. and had had no further attacks of trigeminal neuralgia. There was no history of contact with infectious hepatitis and he had received no injections except venepuncture, by means of disposable needles, during his last admission. The only abnormalities on examination were jaundice and a smooth tender liver, palpable two fingerbreadths below the costal margin.

The carbamazepine was stopped and the following investigations were carried out: Hb 14.8 g./100 ml., W.B.C. 5,400/cu. mm. (differential normal, eosinophils 1%), E.S.R. (Westergren) 50 mm./1st hour, serum albumin 3.1 g./100 ml., serum globulin 4.1 g./

100 ml., with prominent peaks in the α_2 , β , and γ globulins and prothrombin time 11 seconds (control 14 seconds). The urine contained bile and urobilinogen. The initial and subsequent liver-function tests are shown in the Chart.

On 5 March a liver biopsy was carried out. Histological examination showed normal architecture with slight widening of the portal tract and the presence of sparse chronic inflammatory infiltrate. The cells of the limiting plate appeared normal. The hepatic cell plates showed some reduplication and the cells contained considerably increased amounts of pigment.

Because it was by no means certain that his jaundice was due to carbamazepine and because his neuralgic symptoms had responded so dramatically to the drug, it was decided, with the patient's willing co-operation, to give a dose of 100 mg./day and do serial liver-function tests. As can be seen in the Chart, within four days his bilirubin was up to 2.2 mg./100 ml., serum alanine aminotransferase (S.G.P.T.) to 210 units/100 ml., and alkaline phosphatase to 87 units/100 ml. Some bile and a trace of urobilinogen were present in the urine. On stopping the drug the biochemical abnormalities began to improve, but it was not until four months later that the alkaline phosphatase had fallen to 16 units, still slightly above the upper limits of normal.

COMMENT

The association of jaundice with the administration of carbamazepine was shown by a further drug challenge. The jaundice was probably of a mixed cholestatic/hepatic type because both the alkaline phosphatase and the serum alanine aminotransferase were elevated. The liver biopsy was unhelpful as it was done three weeks after the onset of the initial jaundice and the residual histological changes were nonspecific. It is not known why the liver-function tests at the time of drug challenge started to improve while the patient was still on carbamazepine, but this phenomenon has been described in patients receiving chlorpromazine (Haubrich, 1965).

It is of interest that carbamazepine is chemically related to the antidepressant drug imipramine (Tofranil), which may cause a sensitivity type of intrahepatic cholestatic jaundice similar to that produced by the phenothiazines, such as chlorpromazine (Hoaken, 1964).

I am grateful to Dr. Nigel Compston for permission to publish details of this case, to Dr. Roger Williams for his helpful criticism, and to Dr. A. G. Signy and Dr. E. J. F. Spicer for their comments on the liver histology.

IgG Myeloma in Cerebrospinal Fluid with a Total Protein of 32 mg./100 ml.

[WITH SPECIAL PLATE ON FACING PAGE]

Brit. med. J., 1967, 4, 156

The following case is reported because of the finding of an IgG myeloma revealed electrophoretically and immunoelectrophoretically in a lumbar cerebrospinal fluid with a total protein of 32 mg./100 ml.

CASE REPORT

A 47-year-old man had been in good health apart from occasional attacks of "funny feelings" which had troubled him for nine years. These occurred at varying intervals of about three a day to one a month, lasting for 5 to 30 seconds and clearing spontaneously. He said that during these episodes "things go different, things seem to change, and everything looks distant." For the past few years he had also been subjected to grand mal attacks occurring about every two months. He was investigated at Maida Vale Hospital in December 1962, a diagnosis being made of temporal lobe epilepsy. The blood count was within normal limits but the E.S.R. (Westergren) was 20 mm. In September 1965, five months before his second admission, he first noticed attacks of dizziness, especially on looking up, and a tendency to fall to the left coming on about three times a week. In addition, he complained of tinnitus in the right ear.

On examination he was found to be fully alert, and his intelligence was normal. The optic fundi were healthy. The cranial nerves were normal, and so were the upper limbs, trunk, and lower limbs. There was no abnormality in the respiratory, gastrointestinal, and cardiovascular systems.

The E.E.G. was abnormal predominantly in the right anterior temporal region, where episodes of spike and slow-wave discharges occurred. In one of these episodes the patient was apparently unable to respond to command. The air encephalogram and x-ray films of the chest, skull, pelvis, abdomen, and soft tissues were not remarkable. Routine testing for urinary protein was negative, but Bence Jones thermosoluble protein was present in trace amount. E.S.R. (Westergren) 22 mm. Spinal fluid: clear and colourless; 2 cells per cu. mm. (small lymphocytes); total protein 32 mg./100 ml.; Wassermann negative.

A diagnosis was made of temporal lobe epilepsy with no evidence of a space-occupying lesion.

Electrophoretic and Immunoelectrophoretic Studies.—On two occasions we were able to carry out C.S.F., serum, and urinary protein electrophoresis and immunoelectrophoresis. For the simple electrophoresis Kohn's (1958) cellulose acetate technique was used. Three microlitres of serum or C.S.F. (this latter concentrated approximately 100 times) were applied under 120 v. constant current for 45 minutes. A barbitone buffer of pH 8.6 and ionic strength of 0.05 was used. The immunoelectrophoretic studies were conducted by the Scheidegger (1955) modification of the immunoelectrophoretic technique developed by Grabar and Williams (1953) in the serum and by Gavrilescu *et al.* (1955) in the cerebrospinal fluid. Protein was concentrated by the Mies (1953) method. For the immunoelectrophoresis use was made of horse and rabbit anti-normal human sera as well as anti-IgG (Immunology Inc., Chicago). The C.S.F. electrophoresis (Special Plate, Fig. 1a) showed an elevated compact band in the gamma region characteristic of IgG myeloma. This finding was fully confirmed by immunoelectrophoresis (Special Plate, Fig. 1b), which showed the abnormality affecting the gammaglobulin in the corresponding electrophoretic position—namely,

reduplication in the lower part and thickening in the upper arc. These perceptible differences in antigenic specificity were located in the "high speed" area of the gammaglobulin. Fig. 1c (Special Plate) shows the C.S.F. protein immunoelectrophoresis with IgG antiserum bringing up once more the characteristic image of an IgG myeloma. The total serum protein was 9.1 g./100 ml., the electrophoresis and immunoelectrophoresis were showing the same IgG abnormalities as the C.S.F.

A sternal marrow puncture carried out by Dr. M. Batata showed an average normal cellularity with a slight increase in morphologically normal plasma cells but with the presence of a large number of abnormal cells (Special Plate, Fig. 2). These latter were of three types: (a) cells which resembled though were not identical with plasma cells 7–12 μ in diameter (mature variety); (b) large cells 20–30 μ in diameter with abundant pale or dark blue cytoplasm and a large round or oval nucleus, fine chromatin, and sometimes nucleoli; and (c) giant cells with two or more nuclei, the cytoplasm often containing azure granules, clear vacuoles, or having a clear perinuclear zone. The marrow was normoblastic, granulopoiesis was normal, and the megakaryocytes were normal. The appearances were regarded as being consistent with myelomatosis.

COMMENT

The finding of IgG myeloma in a C.S.F. with a total protein of 32 mg./100 ml. is noteworthy. In view of the fact that no symptoms or signs were present to indicate the presence of a myeloma—as so often happens—and that other tests gave no indication either, the importance of the electrophoresis and immunoelectrophoresis is apparent. As the total C.S.F. protein was within normal limits and the blood-brain barrier was apparently unaffected, the protein abnormality found in the C.S.F. is unlikely to have been conveyed through the blood stream, and one must consider the likelihood of its being the local product of myeloma tumour cells.

Plasma cell tumours within the cranial cavity are exceptional, but French (1947) described such a tumour in the third ventricle impinging on the chiasm, but examination of the bone marrow was not made. In our case there was no evidence of a space-occupying lesion within the cranial cavity. In a case of multiple myeloma involving bone marrow and lymph node Kramer (1963) described a tumour within the right temporal lobe consisting of a perivascular proliferation of reticulo-endothelial cells evolving in the same way as in the marrow.

We want to thank the Medical Research Council and the Multiple Sclerosis Society for our respective grants. We are grateful to Mr. V. Logue, Professor W. H. McMenemey, and Dr. H. C. Grant for help and advice.

GROWING POINTS

Spare-part Surgery

NORMAN BROWSE, M.D., F.R.C.S.*

[WITH SPECIAL PLATE ON FACING PAGE]

Brit. med. J., 1967, 4, 157-161

Spare-part surgery began when the first prehistoric man to survive a traumatic amputation of a limb attached a piece of wood to the remaining stump to help himself to walk or grasp. It remained in this phase, with a few exceptions, until the present century, when the combined advances of many different aspects of medicine made possible the insertion of artificial materials and living tissues *into* rather than on to the body.

A notable exception to this recent development is the ancient use of skin grafts. It is often quoted that as long ago as the sixth century B.C. Indian surgeons were moving pedicles of skin from the forehead to the nose to repair severe nasal defects (usually a result of the punishment of "cutting off the nose"). The Italian, Tagliacozzi, gives a description of rhinoplasty using pedicle grafts from the arm in a work published in 1597, and the *Madras Gazette* of 1792 describes in detail the rotation of a forehead flap to the nose. The old maxim "there is nothing new in medicine" comes to mind yet again.

Spare-part surgery can be divided into three sections. Firstly, the attachment of devices to the outside of the body to replace missing parts (*external spare parts*); secondly, the insertion of parts made of foreign dead material into the body; and, thirdly, the insertion of foreign, living, functioning tissue into the body (*internal spare parts*). Each present their own problems, the last being by far the most complex.

External Spare Parts

This aspect of spare-part surgery is well known and it is not intended to discuss the tremendous advances that have been made in this field. Artificial limbs are being improved continually. For example, it is possible to make a power-driven upper limb that can be controlled by the patient from the electrical potentials developed in the muscles of the stump. Although such complex prostheses are seldom required by adults, they may be valuable to children, and the cripples of the thalidomide disaster have been a great stimulus and challenge to the limb-makers. One must not forget that spectacles, hearing aids, false teeth, and even wigs can be defined as external spare-parts. The benefit to mankind of this type of spare-part medicine is incalculable.

For the future this branch of spare-part medicine holds promise of the development of other artificial sense organs. Many years hence we may see an artificial eye relaying its message to the brain, for preliminary experiments have already been performed with this object in mind. Such progress will

be especially important in the replacement and bypassing of organs incapable of repair, such as the optic and auditory nerves.

Internal Spare Parts

Dead and Inert Foreign Materials

Artificial spare parts of metal, plastic, or dead tissues have been of most value in the replacement of those parts of the body that have a simple, relatively inert, mechanical function, such as arteries and joints. Three problems face the surgeon. The first is to insert the prosthesis without infection, for infection around a foreign body almost always results in its extrusion from the host. Secondly, the material inserted must be acceptable to the tissues. The chemical and the physical properties of a prosthesis are important. Vitallium and stainless steel evoke little tissue reaction, and most of the newer plastic materials based on nylon, Terylene, or polyethylene none at all. Nevertheless, even an inert material if it is porous will evoke a foreign-body reaction in response to the changes of tissue and surface tension in and around the pores, and any constituent that is at all water-soluble may cause a chemical inflammatory response. Thirdly, but by no means least, the material must be strong enough to withstand the enormous stresses of daily life. The strains placed on an artificial hip joint by a few years' weight-bearing are far in excess of the stresses and strains that we expect our motor-car engines to withstand. Fortunately the newer metals and plastics are both inert and strong; indeed, much of this field of spare-part surgery could not have developed without the brilliant discoveries of the chemical and other industries.

Artificial Joints

Since 1938, when Smith-Petersen found Vitallium to be a suitable metal for inserting into the body, many types of hip prosthesis have been made. Metal cups have been inserted between the joint surfaces; the head of the femur has been replaced; and in recent years complete joints, acetabulum, and head of the femur have been inserted. Fig. 1 (Special Plate) is a radiograph of a Ring prosthesis, which consists of a cup screwed into the acetabulum and an artificial head of femur. The problem of wear due to friction, not so serious in the older operations where one surface was living and capable of self repair, has not been completely solved and at the moment these prostheses are being inserted only in elderly patients. Time will tell how successful such operations can be. The production of a "frictionless" joint is now being pursued by many workers,

* Honorary Consultant and Assistant Director, Surgical Unit, St. Thomas's Hospital, London S.E.1.

and the complete replacement of the hip joint will probably soon be a common routine procedure.

Apart from the problem of wear at the joint surfaces the orthopaedic surgeon has also to solve the problem of making a permanent joint between the prosthesis and the bone. Occasionally the metal wears right through the bone or, more often, just becomes loose. Much work will have to be done before we have a prosthesis that the skeleton will accept without complaint. Probably this aim will not be achieved until the growth and turnover of the host bone around the prosthesis can be controlled, and the stresses can be transmitted from the prosthesis to the host in a more physiological manner.

Many other joints have been replaced, the finger joints in patients with severe rheumatoid arthritis, the elbow, and the knee. The problems are similar but greater than those of hip prostheses; fixing metal to bone becomes more difficult as the bones get smaller and the mechanics of the joint more complex.

Artificial Arteries

The replacement of arteries with artificial tubes has developed over the last 15 years. The techniques of vascular anastomosis have been understood since the beginning of the century, but suitable materials with which to make artificial arteries have become available only recently. Fifteen years ago the enterprising surgeon simply sewed together two strips of man-made fibre cut almost literally from his shirt-tails, but now we have a vast array of vascular prostheses. Fig. 2 (Special Plate) shows an aortic bifurcation prosthesis made of Dacron (Terylene). One difficulty with these tubes is that they kink when bent, and we still hope to develop a more flexible elastic graft. With such prostheses one can replace a segment of vessel knowing that the holes in it will be effectively stopped by blood clot; that a firm fibrous reaction will develop at the suture line to bind it to the host vessel; and that, provided there is enough blood flowing through, it will not become occluded with thrombus.

These grafts are not perfect. Fig. 3 (Special Plate) is an aortogram of a Dacron aortic bifurcation graft that was inserted five years ago. The left side has become occluded, but the right is patent and looks the same as the day it was inserted. Thus, though the material is strong enough to withstand the arterial blood pressure for many years, it does not conduct blood as well as a normal vessel and thrombosis is a hazard. Two other points must be noted: the disease in the host aorta is still present and slowly advancing towards complete aortic occlusion; and the right femoral artery has been destroyed by the combined effect of the underlying disease and turbulent flow at the anastomosis, so that it has become aneurysmal. Thus partial replacement of an organ may fail because of the progression of the primary disease. As total replacement of the vascular tree is impossible, we will continue to have late failures until we can also cure or arrest the underlying disease. It follows, therefore, that the aim of spare-part surgery should be the complete removal and total replacement of a diseased organ or system.

Artificial Heart Valves

The aortic valve is often so extensively destroyed by disease that repair is impossible. In such circumstances the damaged valve must be replaced with an artificial one or one from another person. The valve most commonly used is the Starr valve (Fig. 4, Special Plate), made entirely of metal and plastic, but freeze-dried aortic valve homografts, taken at necropsy soon after death, are also used. Both may be considered as inert foreign material, for the cells of the freeze-dried valve are dead and disorganized and do not cause an immune response.

Fig. 5 (Special Plate) is a chest x-ray film of a patient with three artificial valves—aortic, mitral, and tricuspid. This is as near as we can go at present towards giving a patient an

artificial heart, but it is unlikely to be long before an artificial pump will be inserted as a long-term replacement for the myocardium.

The heart valve presents another complication of spare-part surgery. The materials of which it is made are inert when placed in soft tissues, but not when placed in a continuous stream of blood. Whereas the normal valve falls back away from the mainstream of blood ejected from the ventricle during systole, the ball of the Starr valve lies right in the middle of the stream. Turbulent flow around the valve may cause sufficient haemolysis to produce anaemia, and if the thrombus around the valve becomes infected a condition identical to sub-acute bacterial endocarditis will develop, which may be fatal.

It is in many ways surprising that either artificial or freeze-dried valves function so well; some Starr valves have been in position for as long as five years and the one-year success rate for these operations is now well above 70%.

Artificial Hearts

The "heart-lung" machine is both an artificial heart and an artificial lung, and is used extensively during cardiac surgery. It is only recently that very small pumps have been devised that can be left connected to the conscious patient to replace or aid the myocardium for long periods.

Fig. 6 shows the principle of these devices. When perfected they will be used when the myocardium is so weak that it is

FIG. 6.—Diagrammatic illustration of an artificial left ventricle used to take the strain off a failing heart in the early postoperative period. Blood is taken from the left atrium and pumped directly into the aorta.

unable to function properly following the repair or replacement of chronically diseased valves, or after myocardial infarction. Thus this device is not an artificial heart, just a temporary artificial left ventricle—though it represents the beginning of another new field of spare-part surgery.

Artificial Nerves

For the Heart.—The commonest conducting system to be replaced with an artificial device is the conducting system of the heart. Failure of ventricular contraction due to a permanent or transient heart block results in hypotension and collapse. Conversely, an excessively fast ventricular rate, as occurs in ventricular tachycardia or auricular flutter, will also cause hypotension and collapse. In either case, whatever the cause, it is necessary to control the heart rate to maintain life. The cardiac pacemaker takes over the role of the sino-auricular node and conducting system. The battery and timing device replace the natural pacemaker (sino-auricular node) and the wires the conducting bundles, the ends of the wires being placed on that portion of the heart that one wishes to control—usually the ventricle.

The problems of implanting wires and fixing them to the heart are no different from those already discussed, but a new

problem arises—the source of power. Early models had the wires coming to an external electrical source, and temporary pacing is still done in this way. This is unsuitable as a permanent method, as the site at which the wires come through the skin is extremely susceptible to infection. Permanent pacing is therefore achieved with either long-life implanted batteries (needing regular renewal) or by induction. In the latter system the wires from the heart are brought to a coil beneath the skin and current is induced therein from an overlying primary circuit (Fig. 7). The source of power is then external, removable, and without any direct connexions with the internal secondary circuit. This overcomes the problems of sepsis, breakage of wires, and renewal of power supply. Recently attempts have been made to harness electric current produced within the body as a source of power.

FIG. 7.—Diagram of the electrical circuit of an inductive cardiac pacemaker.

Perhaps we are not far from the day when a patient may have three artificial heart valves and an artificial left ventricle paced by a pacemaker, which is in turn fired from the electrical activity of right ventricular systole. This, I suspect, is as near as we will get to a truly artificial heart, at least for the next 50 years.

Other Sites.—The development of the cardiac pacemaker is far ahead of all other artificial nerve implants. Electrodes have been implanted on the bladder to stimulate micturition in paraplegics, and attempts have been made to control the sphincter of the bladder to prevent incontinence of urine. Anal incontinence has also been studied, and the most promising approach is the stimulation of the sphincter from the outside with a dumbbell-shaped electrode fitted into the anal canal. These efforts will no doubt lead to the development of permanently implanted electrodes with external inductive power circuits to maintain sphincter competence but which allow it to relax on demand.

A final example of the way in which man is attempting to take over the nervous control of the body is the study of methods of pacing the nerve to the carotid sinus. In the previous examples the battery and wire has replaced an efferent motor nerve. Stimulation of the carotid sinus nerve, on the other hand, is an attempt to mimic the afferent impulses coming from the baroreceptor endings. This aims to effect some degree of regulation of the blood pressure.

Living Autogenous Tissue

In many instances we have within ourselves the tissues required to fashion a spare part. Pedicles of skin can be fashioned into new noses, the ileum can be made into a bladder, the colon can become an oesophagus.

The use of autogenous tissues depends to a large extent on the ingenuity and technical skill of the surgeon. Provided the blood supply of the part remains intact or is re-established, the tissue will live, and often shows a remarkable degree of adaptation to its new function.

Living Foreign Tissue

The problems of placing living foreign tissue into the body are those outlined for inert materials, with the addition of

several greater ones, all yet to be fully resolved. Thus, firstly, one must obtain suitable material. Secondly, the latter must be kept alive during transit from donor to host. Thirdly, it must be kept alive within the host. These problems are best discussed in the context of renal transplantation.

Source of Materials

Organs for transplantation must be living and healthy. The obvious source is another living person, as tests of function can be performed preoperatively and the organ removed at leisure and at a time most suited to the well-being of the donor, recipient, and surgeon. Is it morally and ethically right to ask or expect a healthy subject to donate a kidney? This problem does not arise with other organs such as the liver, heart, or lungs, for the living have none to spare; but, as it is well known that man can live a normal life with one kidney, relatives are often eager to volunteer as donors. Donation is not, however, free from risk. Nephrectomy has its hazards, such as haemorrhage, in addition to those associated with all operations, such as pneumonia and pulmonary embolism. After the donor has survived the operation there is still the possibility of an accident or disease process affecting the function of the remaining kidney. Against these problems must be set the undoubted fact that transplants from live, related donors do better than those from dead, unrelated donors. The problem is one for the individual surgeon concerned. Cadaveric donation has its problems. The best source is the recently dead young person, but there are legal problems concerning the rights of the relatives. Most relatives agree to the removal of a kidney, but it is an essential precaution when the donor is a patient dying in the hospital that the surgeon has nothing to do with the donor's care, lest he should be accused of hastening death in order to obtain the kidney.

Preservation of Organs

Whatever organ is used, and whatever its source, it inevitably undergoes a period of ischaemia between removal and insertion. The effects of this ischaemia are minimized by keeping it as short as possible and by keeping the organ cool. A cold kidney (4° C.) can survive six hours or more of total ischaemia and function. A warm kidney is severely damaged after 30 minutes, but may still recover after one and a half hours of ischaemia.

Any organ must of course be removed in aseptic conditions, and if the donor is alive this is done as an elective procedure in an operating-theatre adjoining that in which the recipient is being prepared. The kidney is then carried from one room to the next, and the ischaemia time is that which is needed to make two vascular anastomoses (10–20 minutes). With cadaveric donors the preparation of the recipient takes longer, as it is begun as an emergency after the donor has died. The kidney is therefore washed through with cold heparinized saline solution and kept in ice until the recipient is ready.

In ideal conditions a transplanted kidney will produce urine as soon as the clamps are removed from the blood vessels. There may follow a diuretic or anuric phase, depending upon the degree of tubular necrosis.

The problems of short-term preservation of the liver, lung, and heart have not yet been solved. To do this the organs will probably have to be artificially perfused with oxygenated blood. In the future one hopes to see banks of viable organs ready for insertion, but the problems of long-term preservation are enormous.

Preparation of the Recipient

Surgeons like to operate on a fit patient, for an ill one is more susceptible to all the common postoperative com-

plications. Patients in renal or hepatic failure are not usually subjected to operation, but in transplantation these are the very subjects with whom the surgeon has to deal. The immediate success of renal transplantation is entirely dependent upon the efficiency of preoperative dialysis. Careful use of the artificial kidney gives a fit patient who can withstand surgery and the postoperative medication with cytotoxic drugs. Without preparation with chronic dialysis the mortality rate is high.

There is no machine to replace the hepatic function, and hence liver transplantation is performed on sick patients. Passing the patient's blood through a pig or human cadaveric liver has not been outstandingly successful in the treatment of hepatic coma. Once an artificial liver is available to prepare the patient liver transplantation will become a practical proposition.

Surgical Techniques

The anastomosis of the vessels of the graft to those of the host is a fairly simple procedure requiring the basic skills of vascular surgery. A kidney is placed in the iliac fossa and its vessels anastomosed to the internal or common iliac vessels. The ureter is either joined to the bladder or to the host ureter. Fig. 8 (Special Plate) shows an intravenous pyelogram of a kidney transplanted to the right iliac fossa; it is indistinguishable from that of a pyelogram of a normal kidney in the loin.

The transplantation of other organs, such as the liver or the lungs, is more difficult, as there are more (usually smaller) vessels to anastomose.

The development of the techniques of transplantation have depended upon work in animals. Many thousands of canine renal, liver, heart, and lung transplants have been performed and techniques perfected, so that the practical problems of inserting the graft into the recipient are now the least of the transplanters' worries.

Prevention of Rejection

Once inside the recipient, perfused with recipient blood, the transplanted organ is subjected to the major hazard of this whole problem—namely, that of host rejection.

From a very early stage in interuterine growth special cells develop, particularly in the thymus, which are capable of recognizing any protein which is foreign to the body. They then migrate to populate the reticuloendothelial system. These "self-recognizing" cells can initiate a series of responses by which any "non-self" material is destroyed. This, in very simple terms, is the basis of immunity. Any cell capable of initiating an immune response is called an immunologically competent cell.

Foreign tissue is destroyed either by antibody production or a local cellular reaction. It is thought that the local cellular response is the most important line of defence. Circulating antigens are released by implanted tissues, but in small amounts, so that there are probably only low levels of circulating antibody.

If one accepts this mechanism of graft rejection then a number of methods of preventing this response become apparent; they are shown diagrammatically in Fig. 9. Only two are of practical value today.

Make the Graft Non-antigenic.—Homozygous twins have an identical genetic make-up. Tissue grafted from one to the other is totally accepted. The results of kidney transplants between identical twins are excellent, some functioning 6–8 years after transplantation. Such good results justify the use of a living donor, but regrettably few patients with renal failure have an identical twin.

Attempts are being focused on ways of typing the tissues of both the donor and recipient to get the best degree of immunological compatibility. These studies are in their infancy and involve many sophisticated techniques.

Recipient and donor should have the same blood group. Leucocytes can also be "typed" in the same way as red cells, but this is a much more difficult procedure.

FIG. 9.—The ways of overcoming the immune response.

A host-versus-graft reaction can be detected before transplantation by injecting the recipient's lymphocytes into the skin of the donor and observing the local reaction. This test can be used only with living donors.

The presence or absence of histocompatibility antigens can also be detected by studying the effect of known specific antigens against donor and recipient lymphocytes. The preliminary results of these attempts at tissue typing are encouraging and suggest that they will have an important role in determining the success or failure of a transplant. If tissue typing is to be used with cadaveric donors the donor will have to be studied before death, so that the methods used will have to become rapid and simple.

Any attempt to destroy the antigenicity of the graft before transplantation always causes death of the transplant.

Prevent the Host Recognizing "Non-self" Material.—Once a foreign tissue is in the body and fully vascularized there is only one way to stop the host recognizing and starting an immune reaction against it—to destroy those cells involved in the recognition process. This is known as immunosuppression. The small lymphocytes are the target cells and there are three possible methods of attack.

Irradiation.—Total body irradiation was the first method to be tried, but was given up when it was found that the dose required to achieve effective immunosuppression invariably killed the host. Local irradiation of the graft is used occasionally to help suppress a severe rejection phase.

Cytotoxic Drugs.—Many drugs have been studied, but by far the most successful is azathioprine (Imuran). Imuran will destroy all types of white cell, and complete depression of marrow and lymph node activity can occur if the dose is not carefully controlled. Cortisone has an inhibitory effect on the reticuloendothelial system and is used in combination with azathioprine. The other cytotoxic drug in common use is actinomycin C.

The present-day successes of renal transplantation are due either to chance histocompatibility or the control of rejection by azathioprine and cortisone, but better substances are needed.

Antilymphocyte Serum.—The wholesale destruction of bone marrow and lymphoid tissue is a blunderbuss approach. Antilymphocyte serum can specifically destroy those cells believed to be responsible for graft rejection. It is made by injecting human white cells into the horse and then preparing the antiserum in just the same way that the antisera against many bacteria are made. Preparations can now be made of pure antilymphocyte globulin. As white cells from many different subjects have to be pooled to get enough for an adequate antigenic stimulus, the antiserum is species—but not individual—specific.

Studies with this substance in man are just beginning ; those experiments that have been performed show great promise. Antilymphocyte serum is the only specific immunosuppressive agent yet developed and those patients who have received it both preoperatively and postoperatively have shown a worthwhile improvement in their tolerance to the grafted kidney.

Current Practice following Renal Transplantation

The usual practice following a kidney transplant is to start the patient on azathioprine and corticosteroids immediately. Renal function is watched carefully. A reduction of renal function indicates the development of the rejection process within the kidney. The earliest change is a reduction of renal plasma flow. The doses of azathioprine and corticosteroids are immediately raised and actinomycin C is added. The signs of rejection usually subside within a few days, and drug doses are then reduced. Episodes of rejection get less frequent and less severe as the months pass, but the patient must be very closely observed for six months, and then seen frequently for the next 12 months. If immunosuppression fails the kidney gets bigger, function fails, the small intrarenal vessels thrombose, and the kidney dies.

In addition to all these problems the surgeon has to manage a patient with a low leucocyte count, who is taking corticosteroids, and who has a wound, drains, and a urethral catheter. The chance of infection is high. These patients are usually barrier-nursed in special units until all the impedimenta of the postoperative period have been discarded.

The one-year survival rate of the graft in good centres is continually improving. Figures of 80 and 90% have been claimed, while the overall world figure for living related donors is about 70%—for unrelated cadaveric donors the figure is about 50%.

Liver Transplantation

A few livers have been transplanted between humans and many have been exchanged between dogs. The latter work has shown the procedure to be technically possible and that the problems of rejection can be met in the same way as kidney transplants. Many animals have survived six months, some as long as a year and a half, but there are no long-term survivors in man.

The functions of the liver are more complex than that of the kidney and certainly less well understood. Thus, though the blood of a man in hepatic coma can be passed through another human or pig liver to lower the concentration of bilirubin and ammonia, there is often no change in the level of coma. A fully functioning transplanted liver would presumably restore a patient in liver failure to normal, but this has rarely been achieved for even a short term with extracorporeal liver perfusion techniques.

At present anyone attempting liver transplantation for hepatic failure must work with a very ill recipient, and the chances of success are slight. With the kidney this problem was overcome by the development of the artificial kidney ; little progress can be expected with liver transplantation until we have an effective artificial liver. It would help in the making of such a machine if we understood the biochemistry of hepatic coma.

Liver transplantation may be valuable to some patients not in liver failure. For example, the patient with an extensive, locally infiltrating, primary carcinoma of the bile duct could be cured if the surgeon could remove the porta hepatis and the liver *en masse*. Liver transplantation may make this possible. The patient, though jaundiced, would not be in hepatic failure and the chances of success would seem to be moderately good.

Liver transplantation will become a practicable procedure when the problems of temporary support for the patient in liver failure and the rapid collection and perfusion of the cadaveric donor liver have been solved.

Other Organs

The transplantation of the heart, lung, pancreas, gut, and endocrine glands are all technically feasible procedures. An ape heart has been inserted into a man, though its function quickly failed. One patient has had a successful pancreas transplant, which is reported to be functioning four months after operation. So continued progress is being made. Any organ that can withstand ischaemia for 30 minutes may be transplanted, and as our knowledge of the immune reactions increases so these transplants can be kept alive for longer periods.

Other Tissues

Perhaps the most important body tissue to be transplanted, and certainly the one that has made all the recent developments of transplantation possible, is blood. Blood transfusion is a form of tissue transplantation, the value of which is inestimable. A major part of modern surgery could not be done without it. The transfer of blood-cell-producing tissues, the bone marrow, has not been so easy. It is beset with all the problems of organ transplantation. Experiments have shown that antilymphocyte serum will improve the results of bone-marrow exchange. If a diseased haemopoietic system could be completely destroyed and replaced with a healthy one a great number of diseases such as aplastic anaemia and leukaemia might become curable.

The future of transplantation is bright. Solving the problems of immunity will solve many of the fundamental problems of cellular biology. Transplanting organs successfully will give life to many. All this will repay the singlemindedness and courage of the few who have pressed on in this field during the last 20 years in the face of failures, discouragement, and seemingly insurmountable barriers.

Paediatric Neurology

[FROM A SPECIAL CORRESPONDENT]

A conference on paediatric neurology was held at the Royal College of Physicians of London on 5 and 6 October. Opening the first session on some aspects of progressive brain disease in childhood, Professor D. V. HUBBLE (Birmingham) observed that no area of paediatrics was more retarded than paediatric neurology. However, the recent genetic and biochemical developments in this field had drawn more attention to it.

Sphingolipidoses

Dr. J. WILSON (London) discussed the neuropilidoses and leukodystrophies, both of which result from derangement of neuronal and glial elements by the abnormal storage of lipids. The neuropilidoses included Tay-Sachs disease, various forms of a similar syndrome of later onset formerly grouped together as "amaurotic family idiocy," Niemann-Pick disease, and Gaucher's disease, in all of which the lipid storage affected mainly the neurones. In the leukodystrophies the white matter was affected; these included metachromatic leukodystrophy, Krabbe's disease, and sudanophilic diffuse sclerosis. The term sphingolipidoses covered both these groups and their many eponymous variations. They presented similar problems, and dementia was a common characteristic. The rate of progression was variable. Early evidence of the syndromes was failure to thrive, arrest of development, and loss of skills already acquired. An acute presentation, perhaps after a febrile illness or an accident, could cause further confusion.

Tay-Sachs disease was the commonest, said Dr. Wilson. The condition was not confined to Jews, and the cherry-red spot at the macula was not specific; it was due to the thinner fovea showing up pink against the surrounding lipid-laden retina. In the group with late onset fits were common, speech was usually affected, and myoclonic jerks were often severe. Blindness occurred late. True cerebellar incoordination and pyramidal lesions could confuse the diagnosis. Onset later than the age of 2 was rare in Niemann-Pick and Gaucher's diseases, and visceral involvement was usually obvious. In the leukodystrophies fits were a less prominent feature and there was peripheral nerve involvement, but the dementia was still the most important feature. In Krabbe's globoid cell sclerosis the onset was before 6 months; the head might enlarge and the legs stiffen, making hydrocephalus and cerebral palsy possible misdiagnoses. Diagnostic investigations included enzyme studies, electroencephalography, and biopsy. Brain biopsy was extremely helpful for guiding the parents and for genetic counselling in atypical cases and in the diseases where other investigations were less definite. Genetic counselling depended on the fact that many of these diseases were transmitted as autosomal recessives and on the increasing ability to identify carriers by biochemical or other tests.

An account of electroencephalographic studies in this group of diseases was presented by Dr. G. PAMPIGLIONE (London). This investigation was important for diagnosis of individual diseases, for screening, for following the evolution of the disease, and for correlation with clinical and biochemical findings. Showing serial E.E.G. tracings in several cases, Dr. Pampiglione illustrated how the E.E.G. was seldom abnormal before there were clinical signs, though the rectal biopsy could be positive before this. However, the E.E.G. was of value in showing that the cerebral disturbance was generalized.

Laboratory Methods

Dr. A. CLAIREAUX (London) said that the histologist was now presented with a wide variety of tissues with which to diagnose sphingolipidoses. Brain biopsies gave the greatest range of information, and at Great Ormond Street Hospital a good-sized piece was usually obtained and divided for routine histology, histochemistry, chemical analysis, and electronmicroscopy. Both grey and white matter was necessary. Between 1962 and 1966 about half of 34 brain biopsies had been positive, while rectal biopsies had given only 30% positive results in 165 cases.

Chemical Classification

Professor J. N. CUMINGS (London) classified the sphingolipidoses according to the chemical groups attached to sphingosine. Techniques were now available to analyse the lipid composition of the grey and white matter. There was no variation between the sexes, but considerable variation at different ages. Specific abnormalities had been found on thin-layer chromatography in Gaucher's disease (though central nervous involvement was rare) and Niemann-Pick disease, but in metachromatic leukodystrophy and Krabbe's disease the abnormality was in the ratio of lipid components. Abnormal quantities of ganglioside were found in Tay-Sachs disease and the amaurotic family idiocy group. Of 178 brain biopsies 77 (43%) had been diagnostic, 37% abnormal but not diagnostic, and 20% normal. There had been no deaths and only occasional fits. At necropsy the area of brain had been found to be healed and the positive diagnoses confirmed.

Management of Progressive Disease

For the session on the management of progressive neurological disease Dr. D. WILLIAMS (London) took the chair. Dr. J. N. WALTON (Newcastle upon Tyne) discussed progressive muscular dystrophy and spinal muscular atrophy. He said that there was no specific treatment for these conditions and accurate diagnosis was the only safe guide to prognosis and genetic counselling.

Clinically the pattern and selectivity of muscle weakness and wasting was important for diagnosis. The electromyogram was more valuable in differentiating myopathy from neuropathy than in diagnosing individual myopathies. Serum enzyme estimations were valuable diagnostically, and muscle biopsy was useful in showing changes not only characteristic of muscular dystrophy and regeneration of denervation but also of recently recognized conditions such as central core disease.

A major problem clinically was the differential diagnosis of the "floppy" infant who was hypotonic from birth. Amyotonia congenita was not a diagnosis but a symptom of many disorders, including central nervous disease, spinal muscular atrophy, myopathies, some benign and not progressive, and diseases of joints and connective tissue. Arthrogryposis multiplex congenita was a complication of similar multiple aetiology.

Dr. Walton went on to outline the general principles of management, which were to avoid inactivity or immobilization even if the child was ill, to watch for contractures and to delay them by stretching the muscles, and to avoid skeletal deformities by the use of light plastic jackets which did not embarrass respiration.

Dr. K. HOLT (London) divided progressively handicapped children into those whose lesions were static, but who nevertheless fell further and further behind their normal fellows, and those whose condition was deteriorating. The latter often had progressive impairment of intellect as well as of physical ability, but this was not always so. Help had to be positive. Training was important to stimulate activity, and ability could improve while the deformity became worse. The ability to do just a little, such as manage one course of a meal alone, was of great value to the patient in morale. If skills were lost other ways had to be found to replace them. In prescribing aids doctors should try to provide things that the patient could manage independently, such as a motorized wheel chair. It was more frustrating to sit in a chair waiting to be pushed than not to have one at all. The morale gained could be easily lost by thoughtless treatment on hospital visits—for example, by being examined by many people as "an interesting case." Steady and continuing care needed a great deal of planning, Dr. Holt concluded. This theme was carried further by the next speaker, Miss M. E. ATKIN (London), who discussed help for the family of the progressively handicapped child. The social worker's job was to share the concern and fears of the parents. The stress of waiting for a diagnosis might be replaced by shock when it came, particularly if an older child already suffered from the same disease. Drawing on her experience of patients at Great Ormond Street, Miss Atkin illustrated how much emotional help was needed, particularly by the mother. In addition, there were many mundane practical problems. Parents' groups

had proved useful for self-help and sharing of problems, and there was scope for much more of this sort of solution.

Vulnerability of the Immature Nervous System

Starting from the hypothesis that slowing the rate of growth of the brain at a time when it was growing fastest would lead to permanent retardation, Dr. J. DOBBING (London) presented experimental evidence that there was a growth spurt in the brain and that interfering with it nutritionally caused lasting effects. Adult animal brains were found not to be affected by such stresses. Thus the brain weight of pigs at one year could be reduced by 33% below that of well-fed litter mates, and after two further years of good feeding it still remained 20% below the controls. Less drastic deprivation occurred in rat litters when 15 infants were fed by one mother and three by another. The overcrowded family was much smaller in both body and brain analysis at weaning and never caught up even on the best subsequent feeding. In humans the fastest rate of brain growth was some time before birth, and Dr. Dobbing thought it possible that the small-for-dates babies might well suffer at the critical time.

Dr. G. PAMPIGLIONE again discussed electroencephalographic findings, this time in the maturation of the puppy, human baby, and piglet. Such studies could be repeated at intervals without harm. Well-recognized patterns of development in each species emerged, which were partly related to the stage of development at birth.

In considering neonatal illnesses leading to chronic brain damage, Professor J. P. M. TIZARD (London) pointed out that some people had to have intelligence quotients below the mean and that most survived the perinatal period unscathed, so that it was important to be wary in attributing causes to deficits. Brain damage appeared to occur in many cases without neonatal illness, and must therefore have occurred in foetal life. Professor Tizard cited experiments in animals in which breathing pure nitrogen caused first dyspnoea, then primary reversible apnoea, spontaneous gasping, and finally terminal apnoea. In monkeys brain damage was found to occur only if the stage of terminal apnoea had been reached. Professor Tizard illustrated the complexities of research into the neonatal period by referring to an old report of the use of oxygen therapy, in which 21% were affected by retrolental fibroplasia and only 4% by spastic diplegia, while another series collected after the dangers of high oxygen therapy were known gave 1% with retrolental fibroplasia and 19% with diplegia. Since 1964 Professor Tizard's unit had monitored the arterial oxygen level in all neonates with respiratory illness, trying to maintain it at

about 75 mm. Hg and not exceeding 160 mm. Of the babies born before 35 weeks' gestation there were 57 survivors, none with retrolental fibroplasia, and four cases of cerebral palsy.

Behavioural Aspects

Dr. P. P. G. BATESON (Cambridge) discussed sensitive periods in the development of animal behaviour. The "critical periods" of the embryologists of 40 years ago had been succeeded by the knowledge that learning was not "all-or-nothing," so the term sensitive was preferable. This could be illustrated by experiments on birds learning to sing. The chaffinch from Somerset learnt a different dialect from the Cambridge one and the song was simpler if the bird was isolated during the first three weeks of life. It could even be taught by a taperecording to sing the final flourish in the middle at this period.

Professor B. M. FOSS (London) said that what was important was to make practical use of the identification of sensitive periods. Unfortunately, the effects of what happened during the sensitive period were not observable for a long time, and there was some confusion in individual instances about whether it was the onset or the offset of the sensitive period which was important. The factors affecting the onset of the sensitive period were probably organic development of the nervous and endocrine systems, passing through the stages of development in correct sequence, and previous learning—for example, to read a child has to be able to look from left to right in steps down the page. The time of offset might be affected by competition between habits, as when congenital cataracts were operated on, and competition between motivation or drives. By analogy with Dr. Dobbing's thesis behaviour might be most vulnerable when developing most rapidly.

Dr. E. J. M. BOWLBY (London) considered the effect of deprivation in early life in those left in a bad institution, and the effect of the disruption of affectional bonds already made. Progressive backwardness could result. In the first group there was inadequate novelty and change, with too many people involved in the child's care. Social responses appeared at the usual time but tended to fade away. Studies had shown that a group fostered by mentally defective women did better in school and subsequently than those with no mother-figure at all. The longer children were left in an institution the less likely they were to settle satisfactorily in a foster home. The bonds to the mother-figure were established between the third and seventh months. It was inadequate and misleading to assume that these bonds were merely related to feeding and pain. Investigation of psychopaths showed a high incidence of the disruption of these bonds. In one series the mother had been absent for more than six months in the first five years

of life in 35% of the psychopaths, but in only 6% of controls. There was a marked tendency for depressives, alcoholics, and addicts to have lost mother or father in the first 15 years of life.

Teale Lecture

Dr. D. B. CLARK (University of Kentucky) gave the Teale Lecture on the subject "Some Speculations on the Pathogenesis of the So-called 'Brain-damaged Syndrome.'" Dr. Clark said that the diagnosis of minimal brain damage was popular, even among grade schoolteachers in America. However, he pointed out, it was certainly not minimal in respect of disability or functional deficit, affecting as it did the abilities which distinguished man from animals. The minimal element was presumably the amount of actual brain damage causing the deficit. However, if this was small it should be possible to localize it. To try to do this he had selected 55 patients with minimal brain damage according to the following rigid criteria. There had to be no affected relatives, no deprivation, no primary emotional factors, no recurrent seizures, no birth trauma, no past or present gross motor defect, no complications, if premature, and an age of less than 30 months at the first visit. Clinically 41 were "clumsy," 18 had mild pyramidal signs, 15 strabismus, and chorea was seen in four. Thirty-six were hyperactive, four emotionally labile, and perseveration was seen in three. Speech was abnormal in all but nine. The E.E.G. was abnormal in 85%.

Clearly several levels of cerebral function were implicated, affecting both sides, and lesions would be slight. Suspicion fell on the brain stem and thalamus—areas seldom examined in the routine necropsy. Examination of brains of babies who died after precipitate labour had shown lesions in the territory of the vertebrobasilar arterial blood supply. Injection of radio-opaque fluid showed that the vertebral artery closed off completely when the head was rotated 35° in the opposite direction. It was recognized that the normal development of nerve cells depended on adequate stimulation, and that nerve cells grew differently after deafferentation. At birth the human thalamus was known to be mature, but the cortex was packed with small immature cells with few processes and few branches. If the thalamic area was destroyed columns of cortical neurones should be affected. Dr. Clark therefore postulated that turning the head during delivery could cause ischaemia in the region of the vertebrobasilar distribution. Some deaths would result but in others the loss of neurones could be minimal, but even losses of 5–10% of cortical cells might be enough to produce the minimally brain-damaged child, while the loss of total brain substance might remain undetectable.

Current Practice

DISEASE OF THE DIGESTIVE SYSTEM

Gastritis

D. N. CROFT,* D.M., M.R.C.P.

What is gastritis? There are many and varied answers. To the layman it is epigastric discomfort and vomiting, particularly related to heavy alcohol consumption. Clinicians find gastritis a convenient term when dealing with virtually any upper abdominal symptom, for it provides a quasi-scientific label with which to satisfy the patient. The gastroscopist's definition of gastritis depends on a visual appearance which has been shown to correlate poorly with the histological state of the mucosa, except when there are acute haemorrhagic erosions. The pathologist diagnoses gastritis by criteria such as the presence of inflammatory cells and the degree of atrophy, but these histological changes may bear little relation to the patient's symptoms. To the haematologist gastritis implies the total gastric atrophy characteristic of pernicious anaemia.

In context the term is reasonable when used by any of these individuals, but because it embraces such a variety of situations gastritis has come to be almost meaningless as a concept of disease. In relation to clinical medicine the term gastritis is best considered as embracing two distinct and probably unrelated entities: *acute gastritis*, which is the transient reaction of the gastric mucosa to irritants, and *atrophic gastritis*, in which the mucosa is permanently altered and its normal function impaired. In both conditions the lesion is diffuse and inflammatory cells are present to a greater or lesser degree, but these two features are the only similarities between acute and atrophic gastritis. In this article the clinical aspects of acute and atrophic gastritis will be considered in relation to recent work on the histology and physiology of the gastric mucosa.

Gastric Cells and Gastric Function

Before considering these diffuse lesions of the stomach it is worth recalling the normal architecture of the gastric mucosa. Our knowledge of the mucosal structure in man has increased greatly in recent years through the use of blind suction gastric biopsy.¹ By this technique samples of mucosa may be simply and safely obtained, and fixed before autolysis of the cells occurs.

The surface of the gastric mucosa facing the gastric lumen is covered with mucus-producing columnar (surface epithelial) cells. These cells are formed by mitoses in the base of the gastric pits and they migrate up the walls of the pits to the surface, where they are extruded into the lumen of the stomach (Figure). In man the life span (or turnover) of these cells is two to four days, and it has been estimated that there is a continuous loss into the gastric lumen of half a million cells per minute.² This active turnover of epithelial cells functions to protect the mucosa from damage.

Below the gastric pits is the glandular or secreting part of the mucosa, where the cells are of a very different type. The two important cells in this part of the mucosa are the large

parietal or acid secreting cells, and the smaller zymogenic or pepsin secreting cells. In terms of turnover these cells are static cells and mitoses are not seen in them. Intrinsic factor, which is required for vitamin B₁₂ absorption, is also produced in this part of the mucosa, possibly from the parietal cells themselves. At the two ends of the stomach, the cardia and the antrum, the normal histological picture is different, for acid and pepsin secreting cells are missing and the mucosa is mainly

Diagram of a histological section through normal gastric mucosa. The epithelial compartment is a dynamic structure composed of columnar cells which are continuously produced by mitoses at the base of the gastric pits. This high turnover of cells probably functions to protect the mucosa from external insults. The cells of the glandular or secreting portion of the mucosa are static; the large circular ones represent parietal or acid secreting cells, and the smaller ones the zymogenic or pepsin secreting cells.

composed of mucus secreting surface epithelial cells arranged as a glandular structure. Gastrin, the hormone which stimulates gastric acid secretion, is produced in the antrum, but from which cell is not known.

Thus the mucosa is composed of two main compartments, a dynamically active surface epithelium which serves to protect the mucosa, and a glandular portion containing static cells which secrete hydrochloric acid, pepsin, and intrinsic factor. Acute gastritis is a transient lesion which affects predominantly the surface epithelium, leaving the gland cells intact. In atrophic gastritis there is permanent destruction of the glandular portion and also important changes in the surface epithelium.

Acute Gastritis

The physiological response of the gastric mucosa to irritants is to exfoliate surface epithelial cells. This was demonstrated in the dog³ in response to 5% ether and 5% clove oil, and in a patient with a gastrostomy in response to 95% alcohol, copper sulphate, hydrochloric acid, and a 1 in 30 suspension of mustard in water.⁴ More recently a similar effect has been shown when three soluble aspirin tablets suspended in 50 ml. saline were

* Senior Medical Registrar and Clinical Chief Assistant to the Radioisotope Department, St. Thomas's Hospital, London.

left in contact with the human stomach for five to ten minutes.⁵ It seems likely that many other substances may have a similar irritative effect on the gastric mucosa; but mild acute gastritis, even to the extent of epithelial cell exfoliation, produces no pain or gastric symptoms. Under these circumstances it is a physiological effect and no clinically significant blood loss or gastric lesion occurs, presumably because of the regenerative capacity of the surface epithelium. Some patients, however, develop epigastric pain and discomfort when they ingest particular irritants, such as aspirin, but this pain is more likely to be due to the presence of a peptic ulcer.

Nevertheless, acute gastritis following the ingestion of irritants can have clinical significance. The patients may present with epigastric pain, nausea, and vomiting as the main features, or with overt or occult gastrointestinal bleeding.

Acute Gastritis Without Bleeding.—This occurs when the stomach is subjected to a large dose of a gastric irritant and may be a feature of ingestion of certain poisons such as lysol. In clinical practice the two most common substances involved are alcohol and staphylococcal endotoxin.

The symptoms of alcoholic gastritis may occur within hours of ingestion but are commonly notable the following morning, when the subject experiences nausea, epigastric discomfort, and vomiting. Gastric biopsy performed during this phase demonstrates damage and denudation of the surface epithelium, with the glandular epithelium left intact.⁶ These histological alterations are transient and the mucosa returns completely to normal in a few days. One or two teaspoonfuls of sodium bicarbonate dissolved in half a glass of warm water and taken immediately on waking offers some relief for alcoholic gastritis.

Staphylococcal gastroenteritis presents with vomiting and diarrhoea. The onset is abrupt and occurs four to six hours after eating contaminated food. Similar alterations in the gastric mucosa to those of acute alcoholic gastritis have been noted, with return of the mucosa to normal within 96 hours.⁶ Staphylococcal gastroenteritis is a self-limiting condition, and though the patient may be acutely uncomfortable for some hours the symptoms subside spontaneously within 12 to 24 hours. Dehydration can occur during the acute phase and may require treatment with intravenous fluids.

Acute Gastritis With Bleeding.—There is now overwhelming evidence that there is an association between haematemesis and melaena and recent consumption of aspirin.⁷ The lesions responsible for this bleeding are haemorrhagic erosions which are probably initiated by the exfoliative effect of aspirin on gastric surface epithelial cells. Haemorrhage occurs with both soluble aspirin and plain aspirin tablets, but as there is evidence that undissolved aspirin particles can "burn" larger holes in the gastric mucosa, it is sensible to advise all patients to take soluble aspirin dispersed in half a glass of water. Alcohol has a similar effect, for it is not uncommon to find diffuse haemorrhagic erosive gastritis when patients are gastroscopied during the acute bleeding induced by an alcoholic bout.

Haematemesis or melaena or both caused by alcohol or aspirin consumption may require urgent blood transfusion, but most of these acute bleeds stop spontaneously within 36 hours, with complete healing of the erosions within a few days. Because of this it is important to establish in a patient with a haematemesis and melaena whether alcohol or aspirin in any form has been taken during the previous few days. If this history is forthcoming and there is no clinical evidence of a chronic peptic ulcer it should incline the physician towards conservative, non-surgical management. A few of these patients, however, will continue to bleed, and under these circumstances an emergency operation will be needed, but the surgical management of these patients can be extremely difficult, particularly if there is bleeding from multiple gastric erosions.

Occult oozing of blood from the stomach occurs in 70% of subjects who ingest two to three aspirin tablets four times per day, usually for rheumatoid arthritis.⁸ This bleeding occurs

whether or not the aspirin is in the soluble form. In most subjects it is of no clinical significance, but in a minority the blood loss may be more than 10 ml. per day, and these individuals are prone to develop chronic iron deficiency anaemia. The bleeding can be substantially reduced by giving enteric-coated aspirin, which can be used in these subjects as long as it controls their rheumatic symptoms. It does not always do so, probably because of erratic absorption. Patients taking aspirin habitually should have regular haemoglobin estimations performed and may require oral or parenteral iron.

Atrophic Gastritis

Unlike acute gastritis, in which the gastric mucosa suffers a transient episode from which it makes a complete recovery, the histological changes of atrophic gastritis are permanent. Atrophic gastritis occurs in association with pernicious anaemia, and also without pernicious anaemia, in which case it is called simple atrophic gastritis. It may involve the whole mucosa or only parts of it. Three main alterations in the histological picture are present.

Atrophy occurs primarily in the glandular portion of the mucosa and may be partial or complete. In pernicious anaemia it is invariably complete with total absence of parietal cells, resulting in histamine-fast achlorhydria.

Inflammatory cell infiltration occurs both in the epithelial compartment and beneath it. Many of the cells are lymphocytes, but polymorphs may be seen infiltrating between surface epithelial cells.

The surface epithelial cells are commonly stunted and abnormal. In severe forms of atrophy the mucosa may alter in such a way as to look like intestinal epithelium with finger-like projections similar to intestinal villi, a condition termed intestinal metaplasia. The turnover of epithelial cells is increased in atrophic gastritis, for there are more mitoses in epithelial cells and a higher loss of these cells into the gastric lumen.²

Cause of Atrophic Gastritis

There is no one cause of atrophic gastritis, but a number of factors are known to be associated with its presence. Age is clearly one of the most important of these, for simple atrophic gastritis is uncommon under the age of 40 and becomes progressively more frequent with advancing age.⁹ Constitutional factors also play a part. The well-known tendency for the gastric atrophy of pernicious anaemia to run in families is one indication of these, and another is the higher incidence of simple atrophic gastritis in subjects with blue eyes.

Gastric autoantibodies occur in the blood of patients with pernicious anaemia and simple atrophic gastritis, which suggests that these conditions are caused by an autoimmune process. However, it may be that the gastric autoantibodies may be merely a secondary phenomenon related to the presence of an abnormal mucosa.

Environmental factors also play a part, for simple atrophic gastritis is commoner in those of low social class. Other environmental factors include heavy alcohol consumption, smoking, hot tea drinking, and possibly habitual aspirin consumption.⁹ An individual over the age of 60 who smokes and drinks heavily has a 60% chance of having simple atrophic gastritis.

Clinical Significance

The most important association between atrophic gastritis and clinical disease is in the case of pernicious anaemia. In this condition there is total gastric atrophy, histamine-fast

achlorhydria, and failure of the stomach to secrete adequate amounts of intrinsic factor. Without intrinsic factor vitamin B₁₂ cannot be absorbed in the terminal ileum; the body runs out of vitamin B₁₂ in the course of four to five years and megaloblastic anaemia ensues.

Most patients with atrophic gastritis do not have gastric symptoms. Some clinicians believe that epigastric pain or discomfort, nausea, and anorexia can be ascribed to this histological change, but there is no real evidence that this is the case. A higher incidence of atrophic gastritis has been found in patients with non-ulcer dyspepsia—indigestion and negative barium meal and/or, negative gastroscopy. However, as atrophic gastritis is commonly associated with gastric ulcer it is possible that these subjects have a gastric ulcer which was missed by barium meal or gastroscopy. In our present state of knowledge it is better to regard atrophic gastritis as predisposing to gastric ulcer.

Rarely, patients with simple atrophic gastritis suffer from recurrent bleeding from gastric ulceration.¹⁰ This is certainly not the case in most patients with this condition; in fact there is some evidence that subjects with atrophic gastritis may be protected against aspirin-induced occult gastrointestinal bleeding.⁸ On the other hand, haematemesis and melaena induced by aspirin do appear to occur from acute erosions which have developed in areas of atrophic gastritis.¹¹ This suggests that under certain circumstances aspirin initiates acute bleeding from susceptible, atrophic areas of the gastric mucosa.

For many years it has been known that patients with recurrent iron deficiency anaemia may be achlorhydric, and more recently they have been found to have a higher than expected incidence of atrophic gastritis. Iron deficiency associated with atrophic gastritis cannot be adequately explained by chronic bleeding or failure of iron absorption. Other possible mechanisms involved include the production by gastric mucosa of an iron binding protein, or an excessive rate of loss of iron into the gastric lumen in exfoliated gastric epithelial cells. With regard to the latter it is interesting to note that patients with simple atrophic gastritis associated with iron deficiency anaemia have higher than normal cell loss from the gastric mucosa as measured by gastric D.N.A. (deoxyribonucleic acid) rates.²

Some 5–10% of subjects with pernicious anaemia develop carcinoma of the stomach. Even in patients without pernicious anaemia carcinoma of the stomach arises in atrophic gastric mucosa. A factor predisposing to cancer in atrophic gastritis is probably the higher than normal turnover of epithelial cells in this condition. The turnover of epithelial cells is particularly high in areas of intestinal metaplasia² which are the sites of atrophic mucosa that are most premalignant.¹²

Atrophic gastritis, even when diagnosed by gastric biopsy, does not merit treatment. Its finding should alert one to the possibility of associated conditions such as gastric ulcer, carcinoma of the stomach, pernicious anaemia, or recurrent iron deficiency anaemia, which require their own specific treatment. The recent finding that administration of corticosteroids will improve the secretory capacity and histological appearance of the atrophic mucosa of pernicious anaemia in no way implies that these drugs should be used to treat patients with atrophic gastritis.

Rare Forms of Gastritis

Menetrier's disease is a diffuse disorder of the stomach in which the mucosa becomes thickened and hyperplastic. Radiologically giant rugal folds are seen. An important feature of this condition is that patients may present with oedema due to

hypoproteinaemia. The hypoproteinaemia has been shown to be due to excessive loss of protein from the abnormal gastric mucosa. The disease is very rare, but is notable as it was the first condition in which protein-losing gastroenteropathy was described.

True infective gastritides have been described due to bacteria, syphilis, and tuberculosis. These are extremely rare and can only be regarded as medical curios.

Conclusion

To the clinician the term gastritis embraces two distinct and probably unrelated entities.

(1) Acute gastritis is a transient response of the gastric mucosa to the ingestion of irritating substances such as alcohol, staphylococcal endotoxin, and aspirin. The symptoms of excessive intake of these substances include epigastric discomfort, nausea, and vomiting. Haematemesis and melaena may occur from gastric erosions, and in Britain it is particularly associated with aspirin consumption.

(2) Atrophic gastritis is a permanent atrophy which affects part or all of the gastric mucosa. Total atrophy is a feature of pernicious anaemia. The cause of simple atrophic gastritis is not known, but in susceptible individuals it occurs particularly over the age of 50 and appears to be related to heavy alcohol consumption and smoking. It is commonly associated with other clinically important conditions; in particular with gastric ulceration, recurrent iron deficiency anaemia, and gastric carcinoma. The alteration in the gastric mucosa may be involved in the pathogenesis of these conditions, but only research will determine their exact relationship one to another.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Hazards of High Flying

Q.—I understand that air hostesses on some lines are grounded for six months' rest after two years' flying. Why is this, and what, if any, are the hazards to their health from (1) pressurized cabins, and (2) radiation?

A.—The work of air hostesses may be physically tiring. They carry out their duties at the equivalent altitude of 5,000–6,000 ft. (1,524–1,828 m.). On short sectors their work load is heavy, because of the limited time available to serve a full complement of passengers. On long-haul operations they may be flying to, through, and from the tropics, with irregular hours, irregular meals, and without sufficient time to acclimatize or adapt themselves to environmental changes. Flying east or west may also cause upset to the normal circadian rhythm and an associated disturbance to the sleep pattern. These factors, which may predispose to fatigue, are easily remedied by adequate pre-flight and postflight rest periods.

There is, however, no valid medical reason why air hostesses should be grounded for six months' rest after two years' flying. It is possible that some airlines may temporarily employ air hostesses on the ground for special training or other reasons, but this would not be dictated by medical considerations. In fact, many of the international airlines have a 10-year flying contract for their air hostesses.

There is no known hazard to health from flying in pressurized aircraft where the simulated altitude is of the order of only 5,000–6,000 ft. The cabin temperature is controlled, and the rate of change of air in the existing V.C.10 is over 1 lb. (0.45 kg.) of fresh air per person per minute. The Olympic Games in Mexico City will be held at a similar altitude, and there are many other areas of the world above these altitudes where non-acclimatized visitors suffer no ill-effects.

There is no hazard to health from radiation in travelling by modern jet aircraft at altitudes of up to 40,000 ft. (12,192 m.). Many reliable airlines continue to monitor their aircraft cabins, and no hazard has been found to exist for passengers or crew. Even with the advent of supersonic aircraft operating at 60,000 ft. (18,288 m.) radiation will not be a problem, except possibly from solar cosmic events. These occur probably only once or twice in a year of maximum solar activity in the 11-year solar cycle. Such occasional and remote phenomena may lead to some operational limitations, but no radiation exposure hazard to passengers or crew will be acceptable.

Cobalt-labelled Vitamin B₁₂

Q.—Are the recently available ⁵⁷Co-labelled cyanocobalamin capsules adequate in the performance of the Schilling test?

A.—Radioisotopic cobalt-labelled vitamin B₁₂ has been used for some time in the investigation of the macrocytic anaemias.

More recently the isotope ⁵⁷Co has been used to label the vitamin. This isotope has a half-life of 270 days. It emits no particulate energy but one gamma ray (0.123 MeV). Though it has a longer half-life than ⁵⁸Co, its emission is probably safer for human use, since the liver irradiation produced by ⁵⁷Co is about one-tenth of that produced by the same dose of ⁵⁸Co.¹

Workman and Rusche,¹ investigating serum levels of ⁵⁷Co-labelled vitamin B₁₂ as a basis for an absorption test, compared the new method with the Schilling test. They gave 0.56 µg. vitamin B₁₂ labelled with 0.56 µCi ⁵⁷Co to fasting patients in the form of a capsule. A 24-hour urine collection was started immediately. 1,000 µg. of non-radioactive vitamin B₁₂ was given parenterally two hours after the ⁵⁷Co-labelled B₁₂. The total urine volume was measured and a 100-ml. aliquot counted in a 2 by 2 in. (5.1 by 5.1 cm.) crystal well-type scintillation counter. The dose excreted was 7 to 37% of the ingested dose in normals, whereas patients with pernicious anaemia never excreted more than 7%.

Vitamin B₁₂ labelled with ⁵⁷Co has also been used by Forshaw and Harwood in a similar investigation. It was evident that ⁵⁷Co vitamin B₁₂ was satisfactory for the Schilling test, though this test will, of course, still suffer from the inherent disadvantages of inaccuracy in patients with poor renal function, or in those who are unable to collect a complete sample of urine, and from the need to give a large dose of vitamin B₁₂ as a flushing dose.

Drugs, Diet, and Porphyria

Q.—What drugs and foods are contraindicated in a patient with porphyria?

A.—The following drugs are contraindicated in hepatic porphyria: any barbiturate or sulphonamide; drugs containing oestrogen (for example, oral contraceptives); griseofulvin; glutethimide; phenytoin sodium; meprobamate; bemegride; methsuximide and phensuximide; methyprylone; chloroquine; tolbutamide and chlorpropamide; possibly methyl dopa; and dichloralphenazone. In addition, there are several drugs not in current use which are contraindicated—for example, apronal, sulphonal, and trional. This list is based on clinical and experimental studies,¹⁻³ and more recently on an in-vitro screening technique which allows the testing of the effect of drugs on the porphyrin synthesis of chick embryo liver cells.⁴

These drugs should not be used for patients, or near relatives of patients, with hepatic porphyria, which is the most common and important type of the disease and includes acute intermittent porphyria, porphyria variegata, cutaneous hepatic porphyria, and hereditary coproporphyria.

There is no evidence that drugs have adversely affected the very rare congenital erythropoietic porphyria, in which the bone marrow but not the liver is involved in the porphyrin dyscrasia. There is some evidence that in the much more common erythropoietic protoporphyria the porphyrin metabolism of the liver as well as of the bone marrow is abnormal. For this reason the drugs noted above should be avoided in this disease.

No item of diet, apart from alcohol, is contraindicated in porphyria. There is evidence, however, that a diet ample in carbohydrate and protein is beneficial to patients with porphyria.⁵ In my experience one patient developed a very severe attack of acute porphyria when she put herself on a very low calorie diet for obesity.

Inheritance of Amyotonia Congenita

Q.—A woman has had two children, of which the first had amyotonia congenita (and died in infancy) and the second is normal. What are the chances of (1) further children of the woman being affected, and (2) the children of the normal boy being affected?

A.—Amyotonia congenita of the form which is best called "infantile progressive muscular atrophy" is an autosomal recessive condition.¹ Therefore the chance of recurrence in future children of this woman is one in four, and the chances of the offspring of the normal boy being affected are small. By the time he grows up it may be possible to test whether he is a heterozygote and, if so, whether his fiancée is also a heterozygote.

Clothing for Tropics

Q.—Is underwear and clothing made of synthetic material better for tropical wear than wool or cotton material?

A.—Cotton and wool fibres absorb water, but synthetic materials such as orlon, nylon, etc., do not. In a hot climate the sweat rate is high, and it is uncomfortable to wear vapour- or water-impermeable clothes.

The earliest version of nylon shirts were distinctly unsatisfactory to wear, since sweat accumulated underneath the shirt. Since then techniques of weaving have improved, mixtures of cotton and synthetic fibres are used, and the disadvantage of water-impermeability has been reduced, though it cannot be abolished.

The advantages of clothes made from synthetic fibres include light weight, ease of washing, and durability. In practice, a useful compromise is to have cotton underwear and suits made of synthetic fibres, preferably mixed with wool or cotton.

Book Reviews

Adrenal Function

The Adrenal Cortex. Edited by Albert B. Eisenstein, M.D. (Pp. 685+xiv; illustrated. £8.) London: J. & A. Churchill. 1967.

So much of our modern knowledge of adrenal function is based on work done in the United States that a textbook on the subject from that country is an event of major importance. Practically all the 26 contributors to this volume have already gained world-wide renown for their experimental work in this field, and all students of the adrenal cortex will recognize its authority from the names of Baulieu, Liddle, Luetscher, Migeon, and Yates, to give but a few representative examples.

Although mainly a review of existing knowledge, the book does contain an appreciable amount of original work, as, for example, in the chapter on physiological control of adrenal cortical secretion. This section, using computer analogy, regards the mechanism as "a restricted signal, multiple input closed loop control with cortisol sensitive and insensitive pathways." The emphasis tends to be rather more on physiological background than on strictly clinical applications, but the scope is so wide that there

is inevitably a fund of information of direct interest to all clinical endocrinologists. Treatment aspects are particularly well handled in the chapters on adrenal insufficiency and on adrenogenital syndromes, both of which deal thoroughly and clearly with their difficult subjects.

An excellent and informed chapter on the synthetic analogues reveals how intense has been the research, and how great the knowledge gained of the effects on activity of structural modifications to the hydrocortisone molecule. In contrast a chapter on general metabolic effects reveals how little we yet know about the action of corticosteroids on immune phenomena and on thymus function, and a chapter on electron-microscopic changes in adrenal cells leaves one with the impression that an explanation of the changes in terms of function is still very uncertain. Perhaps the most stern test of a review of disorders associated with altered aldosterone secretion is its handling of the oedematous states. Even by this criterion this section

is wholly admirable. Indeed, all the sections are constructively critical in a way which is possible only to those who, by personal research in the subject, have developed a true "feel" for their problem.

British workers on adrenal problems may be surprised to read that fluorimetric methods of plasma corticosteroid estimation are regarded as requiring too much care and caution for the average clinical laboratory. The important analysis of the mode of action of triparanol on the adrenal which was carried out by one of the contributors is not referred to in another chapter where the subject is discussed. It is of interest to compare the chapter on Cushing's syndrome, which offers only one non-U.S. reference, with that on adrenogenital syndrome, where 130 of 384 references are to non-American sources.

But these are minor criticisms. This volume will be needed by all medical libraries, even though expensive, and will be very frequently referred to by all adrenal endocrinologists. It is clearly destined to become a standard work of reference on its subject.

C. L. COPE.

Amphetamine Effects

The Amphetamines. Toxicity and Addiction. By Orania Josseau Kalant, Ph.D. (Pp. 151+xii. 48s.) London: Oxford University Press. 1967.

Dr. Kalant has produced a valuable review of the literature concerning the toxicity of amphetamines in man and the characteristics of amphetamine abuse.

She considers the effects of acute and chronic amphetamine intoxication, giving representative case histories, and, drawing on Connell's 1958 study of 42 cases, describes amphetamine psychosis. She comments that it is impossible to judge from the literature how many people take amphetamines habitually without suffering any ill effects. At the same time she warns that psychotic reactions from the use of amphetamine are more common than is perhaps still realized, and that routine chemical tests for amphetamines in schizophrenic patients are important.

There is a useful review of the vexed question of what is meant by the terms drug addiction, habituation, and dependence. Dr. Kalant concludes that addiction to amphetamines does occur. She discusses the effects of amphetamine abuse on the individual and society, both in Great Britain and in other countries. Finally she discusses the dangers of amphetamine-like drugs.

This is a well written, up to date, objective review of a subject which is all too often distorted by prejudice and purple journalism.

PETER DALLY.

Radiotherapy

The Biological Basis of Radiation Therapy. Edited by Emanuel E. Schwartz, M.D. (Pp. 624+xvi; illustrated. £7.) London: Pitman. 1967.

During the last 50 years radiotherapists have accumulated a vast practical experience in the radiation treatment of cancer. Since the second world war the growing number of hospital physicists have helped to transfer this practical experience from one radiotherapy centre to another by accurately measuring the radiation dose distribution in the treatment field, so that the observed clinical responses could be related to accurate physical measurements of radiation dose. In more recent years a new phase of development of radiotherapy has occurred in which the basic disciplines of biology, biochemistry, and biophysics have played an interlocking role. Although these developments have not yet had a great deal of impact on clinical practice, apart from a few notable exceptions such as the oxygen effect, they are beginning to give a better understanding of why the radiotherapy techniques built up from years of practical experience have been so effective.

The book under review contains 10 chapters, each written by a specialist, dealing with different aspects of the biological basis of radiotherapy. The first two chapters contain reviews of the biophysical and biochemical effects of radiation at the molecular level, and the third chapter is concerned with radiation effects at the cellular level. These subjects are the basis of radiotherapy, and in this book the individual authors deal com-

petently with their material in the 120 pages available to them.

There is some overlap between the next two chapters, which deal with the pathological effects of radiation and radiation injury in man, but this is not sufficient to make either of the chapters unnecessary.

In the sixth chapter, the longest in the book, Dr. L. Cohen has undertaken the difficult task of relating the principles of radiobiology obtained from experiments at the cellular level to the clinical practice of radiotherapy. The term R.B.E. is unfortunately given two different meanings in this chapter. In Table 6-2, R.B.E. is used in the conventional manner, whereas in Table 6-5 the reciprocal of this value is also called R.B.E. Again there is some confusion about which word is abbreviated to E. In the original paper on this subject, published in 1931, Failla and Henshaw definitely used "effectiveness" and not "efficiency" as in this chapter. However, these are minor criticisms of a chapter which should prove extremely interesting to those practising radiotherapy.

The next chapter deals with modifications of radiation response by means of oxygen or chemical compound techniques, which are becoming more widely used in clinical practice. The biochemistry of cancer cells is reviewed in the eighth chapter. As yet cellular biochemistry has had little bearing on clinical practice, but undoubtedly a better understanding of it could lead to more efficient treatments in the future.

The last two chapters review the influence of the host on tumour growth and the influence on radiotherapy of the experimental

treatment of tumours in animals. These two chapters emphasize that there are many factors which may influence the growth of tumours other than the tumour cells *per se*.

In summary this book contains a wealth of information which is indicated by the number of references given at the ends of each chapter amounting to more than 2,300. It should be particularly useful to those starting in the field of radiotherapy and a valuable teaching aid in medical schools.

G. W. DOLPHIN.

Factual Account of Communicable Diseases

Infectious Diseases. By A. Melvin Ramsay, M.A., M.D., and Ronald T. D. Emond, M.B., Ch.B., M.R.C.P., D.T.M.&H. (Pp. 306+xii; illustrated. 63s.) London: William Heinemann, 1967.

For some years there has been a need for a well-illustrated text on British practice in communicable diseases and this book by Dr. Ramsay and Dr. Emond fills the gap satisfactorily. It is an essentially factual account. The few opinions expressed are of necessity dogmatic in a book designed for students, but the factual approach does lack the impact of descriptive writing. For example, a student who has never seen a case of mononucleosis is not presented with any clear pictures of what such a patient actually looks like. Perhaps this is a harsh criticism, as medicine can only really be learnt at the bedside. The virology is up to date and nicely presented with excellent electron photomicrographs. Considering the price is only three guineas the colour reproductions are more than satisfactory and many of them are very helpful. At the end of the book there are useful tables concerning isolation and quarantine practice and the brief chapter on "P.U.O." gives excellent advice on the investigation of this common problem.

Brevity leads to dogmatic statements with which not all would agree. For example, "the downward course of the eruption (in measles) is so constant that any other course would exclude the diagnosis"; "exposure to chicken-pox sometimes causes herpes zoster"; "vaccination does not offer protection against haemorrhagic smallpox"; and "scarring in flat smallpox is deep." Desquamation of the severity shown on Plate 7 nowadays follows other erythemas much more frequently than scarlatina, so the caption is somewhat misleading. In the chapter on meningitis no indication of the quantity of cellular and biochemical changes in the cerebrospinal fluid is given and, more important, there is no mention of the very real diagnostic difficulty of the "half-treated" case which can so readily mimic aseptic meningitis. Surely few of us now use parenteral, as opposed to oral, penicillin in the routine treatment of streptococcal infections.

The references are somewhat unbalanced (for example twenty-four for "rubella," none for "acute meningitis") and do not always fall into the category of "recommended further reading for students."

These are minor criticisms which do not detract from the general value of the text,

over which a great deal of care has clearly been taken. The authors and publishers are to be congratulated on producing a well-illustrated book containing up-to-date information about the common communicable diseases in Great Britain at a remarkably reasonable price.

G. DONALD W. MCKENDRICK.

What is Known about Lymphocytes

The Lymphocyte in Immunology and Haemopoiesis. Symposium, Bristol, 1966. Edited by J. M. Yoffey. (Pp. 376+viii; illustrated. £6.) London: Edward Arnold, 1967.

The Lymphocytes. By Michael W. Elves, B.Sc.(Notts), Ph.D.(Manch.). (Pp. 303; illustrated. 50s.) London: Lloyd-Luke, 1966.

Until comparatively recently the lymphocyte was looked upon by haematologists as a blood cell of characteristic morphology but dubious function and by histologists as being concerned in an ill-defined way with the body's responses to chronic infection. Now, as one result of the almost explosive development of the science of immunology, it is regarded as a cell of key importance, and a great deal of research on its functions is being undertaken by medical scientists and biologists.

The larger of the two volumes under review—*The Lymphocyte in Immunology and Haemopoiesis*—records the proceedings of a large-scale international symposium which was held in Bristol in April 1966 under the general direction of Professor J. M. Yoffey. In summary, it consists of 43 short to medium-length papers, with references but without discussion, and without index, which cover a representative but very wide field of experimental studies in relation to lymphocyte physiology and function. Among the main topics dealt with in well illustrated and documented papers are the morphology and embryology of lymphocytes, the response of normal and pathological lymphocytes to phyto-haemagglutinin, lymphocyte kinetics and circulation, the possible role of "lymphocytes" as pluripotential stem cells, their role in immunity, including the homograft reaction, experiments with anti-lymphocyte serum, and the thymus and lymphocytes.

The completed volume is a valuable record for the research worker in the lymphocyte field, but the reading of it is likely to prove hard going for the general physician or clinical haematologist, who may feel disappointed that of the subjects in which he is particularly interested the lymphoproliferative diseases are not dealt with in detail and the syndromes associated with deficient lymphocytopoiesis and the nature of the lymphocyte response in infectious mononucleosis are not mentioned. The reviewer would have welcomed, too, a final chapter summarizing the whole subject, admittedly not an easy task in a rapidly expanding field.

In the smaller of the two volumes, *The Lymphocytes*, Dr. M. W. Elves has attempted to present an up-to-date review of what is known about lymphocytes in one medium-sized volume. Starting with anatomy and physiology, he deals with circulation, lifespan, and production, then the lymphocyte's

role in inflammation and repair and in antibody production, and its role in transplantation immunity. Next, there are chapters on lymphocyte transformation and the possible function of lymphocytes as stem cells and trephocytes. Finally, there is a short and useful section entitled "Some Conclusions" in 16 brief paragraphs. The main text is followed by an extensive bibliography of 777 references, with titles, and an index.

Dr. Elves's book is well conceived and a brave attempt is made to present a critical review of a difficult subject. However, the book is not easy to read, and in places—and this is not Dr. Elves's fault—it reads like a catalogue of discordant results and false interpretations. All in all, however, of the two books now being discussed that of Dr. Elves would seem to be the more useful to a pathologist or physician who wishes to bring himself up to date in a difficult field. The book is illustrated rather sparingly with 43 figures, mostly line diagrams and photomicrographs. Some of the latter are of rather poor quality and the text is marred by occasional infelicities of style.

J. V. DACIE.

Girls Growing Up

Adolescent Gynecology. Edited by Felix P. Heald, M.D. (Pp. 163+x; illustrated. 72s.) Edinburgh and London: E. & S. Livingstone, 1966.

This attractive little volume reports the proceedings of a seminar supported by the Department of Health Education and Welfare of the United States. But when it was held, and where, is not revealed. It must have been a good meeting, since well-known and excellent speakers—including J. W. Goldzieher, R. B. Greenblatt, C. W. Lloyd, A. L. Southam, and S. H. Sturgis, invidiously perhaps to select but a few—took part. No doubt the papers all sounded well when given, but some read rather too colloquially and repetitively. More ruthless editing would have been advantageous, but one can well sympathize with the editor's difficult task in this situation.

The scope of the work is best indicated by the subjects covered: Janet McArthur on the reproductive endocrinology of adolescence; Lloyd on the biochemistry of steroids and hormones; Goldzieher on the identification of sex hormones by chemical and biological assays (a controversial and stimulating essay, this, emphasizing the necessity of regarding endocrine laboratory data with caution); Anna Southam on metropathia haemorrhagica and non-psychogenic amenorrhoea; Sturgis on the management of congenital defects; F. P. Heald on ovarian tumours during adolescence; V. B. Mahesh and R. B. Greenblatt on hirsutism; A. M. Burnett on vaginitis; W. J. Dougherty on public health aspects of venereal disease; A. E. Marans on the psychological impact of pregnancy on the adolescent girl; and S. L. Werkman on sex education in adolescence. There is an index, but it is somewhat sketchy and incomplete.

From a number of points of view the adolescent girl is requiring increasing attention from the doctor and since she fits neatly into neither the province of the paediatrician,

nor that of the gynaecologist it is obviously the family doctor to whom she ought most readily be able to turn for advice. This book could certainly provide him with a timely and useful refresher course.

G. I. M. SWYER.

International Council of Nurses

A History of the International Council of Nurses. 1899-1964. The First Sixty-Five Years. By Daisy Caroline Bridges, C.B.E., R.R.C., S.R.N., S.C.M., F.R.S.H. (Pp. 254 + xxi. 40s.) London: Pitman. 1967.

On 1 July 1899, at the annual conference of the Matrons' Council of Great Britain and Ireland, Mrs. Bedford Fenwick proposed "that steps be taken to organize an International Council of Nurses." The resolution was carried and a provisional committee appointed, which at its meeting next day authorized the English members to draw up a constitution and circulate it to interested

parties. A year later the constitution was adopted, Mrs. Bedford Fenwick elected the first president, and Miss Lavinia Dock honorary secretary. Between 1901 and 1912 congresses were held at Buffalo, Berlin, Paris, London, and Cologne, but we are told that "it was inevitable that with no established office or secretariat, and with the president and honorary secretary divided by the Atlantic Ocean, very little work could be undertaken between meetings."

The intervention of the war of 1914-18 made matters more difficult, but in 1922 changes were made, a full-time secretary was appointed, and an office established in Geneva. The new secretary, Miss Christiane Reimann, was a very capable hard-working officer who visited many European countries and greatly advanced the membership and influence of the council during her 12 years of office. She was succeeded by Miss Anna Schwarzenberg, whose ability to speak seven languages was of great assistance. The war of 1939-45 made it necessary to move the headquarters first to London and then to New York. After peace was declared the office was again established in London, and

the secretariat was increased and reorganized, so that when Miss Bridges was chosen as chief executive officer in 1948 she was able to do much more field work in different parts of the world, thus increasing the usefulness and influence of the International Council. Between 1948 and 1961 a conference was held at Stockholm and congresses in Petropolis (Brazil), Rome, and Melbourne, and membership of the I.C.N. was increased by the addition of over 30 countries. The present headquarters is again in Geneva, and the executive director is Miss Helen Nussbaum. At the congress held at Frankfurt in 1965 there was an assembly of 6,000 nurses from 63 countries—good evidence of a thriving organization.

The story is well told in a pleasing style, controversial points are gently dealt with, and credit given where credit is due. The illustrations are very good and tell a story of their own. The book should appeal to all nurses and to those medical practitioners who wish to keep themselves well informed about the achievements of a sister profession.

ZACHARY COPE.

Books Received

Review is not precluded by notice here of books recently received.

Transport und Funktion Intracellulärer Elektrolyte. Symposium in Schönen, 1967. Edited by F. Krück. (Pp. 299; illustrated. DM. 32.) Munich: Urban & Schwarzenberg. 1967.

Modern Trends in Pathology—2. Edited by T. Crawford, B.Sc., M.D.(Glasg.), F.R.C.P., F.R.C.P.(Glasg.), F.C.Path. (Pp. 323 + vii; illustrated 85s.) London: Butterworth. 1967.

Lecture Notes in Pharmacology and Therapeutics for Nurses. By James A. Boyle, M.D., M.R.C.P. (Pp. 228; illustrated. 25s.) Edinburgh and London: E. & S. Livingstone. 1967.

The Vitamins. Chemistry, Physiology, Pathology, Methods. 2nd edition. Vol. 1. Edited by W. H. Sebrell, jun., and Robert S. Harris. (Pp. 570 + xiii; illustrated. £10.) New York and London: Academic Press. 1967.

Viral and Rickettsial Infections of Animals. Vol. 1. Edited by A. O. Betts and C. J. York. (Pp. 388 + xi; illustrated. £6 8s.) New York and London: Academic Press. 1967.

Surgery of the Ear. 2nd edition. By George E. Shambaugh, jun., M.D. (Pp. 722 + xi; illustrated. £10 10s.) London: W. B. Saunders. 1967.

Radiology in Neuro-Ophthalmology. By Guido Lombardi, M.D. (Pp. 244 + viii; illustrated. £5 6s.) Edinburgh and London: E. & S. Livingstone. 1967.

Introduction to Psychotherapy. Its History and Modern Schools. By J. A. Hadfield. (Pp. 363. 50s.) London: George Allen & Unwin. 1967.

Medizinische Radiologie. By Professor Joachim Atndt. (Pp. 375; illustrated. No price given.) Jena: Gustav Fischer. 1967.

A Guide to the Identification of the Genera of Bacteria. With Methods and Digests of Generic Characteristics. 2nd edition. By V. B. D. Skerman. (Pp. 303 + xii; illustrated. 78s.) Edinburgh and London: E. & S. Livingstone. 1967.

Quantitative Problems in Biochemistry. 4th edition. By Edwin A. Dawes, Ph.D., D.Sc., F.R.I.C. (Pp. 351 + viii. 37s. 6d.) Edinburgh and London: E. & S. Livingstone. 1967.

Medicine in Medieval England. By C. H. Talbot. (Pp. 222. 35s.) London: Oldbourne. 1967.

New Trends in Basic Lymphology. Proceedings of a Symposium held at Charleroi, Belgium, 1966. Edited by J. M. Collette, G. Jantet, and E. Schoffeniels. (Pp. 235; illustrated. Fr. 48.) Basel and Stuttgart: Birkhäuser. 1967.

The McPherson Experiment. Expanding Community Hospital Services. By John R. Griffith, Lewis E. Weeks, Ph.D., and James H. Sullivan. (Pp. 337; illustrated. \$10.) Ann Arbor, Michigan: Bureau of Hospital Administration. 1967.

The Origins of the National Health Service. The Medical Services of the New Poor Law, 1834-1871. By Ruth G. Hodgkinson, Ph.D. (Pp. 714 + xvii. £6 6s.) London: Wellcome Historical Medical Library. 1967.

Ophthalmic Eponyms. An Encyclopedia of Named Signs, Syndromes, and Diseases in Ophthalmology. By Spencer P. Thornton, M.D. (Pp. 324 + ix. No price given.) Birmingham, Alabama: Aesculapius. 1967.

Functional Bandaging. Including Splints and Protective Dressings. By Seymour W. Meyer, M.D., F.A.C.S., D.S. (Pp. 294 + viii; illustrated. 75s.) Barking, Essex: Elsevier. 1967.

A Manual of Abdominal Operations. By R. M. Kirk, M.S., F.R.C.S. (Pp. 208 + xvi; illustrated. 30s.) London: Pitman. 1967.

Funktionelle Neurologische Diagnostik. Volume 3. Gehirn. Edited by Dr. Harri Joschko. (Pp. 332 + xxiii; illustrated. £5 2s. 5d.) Jena: Gustav Fischer. 1967.

Correspondence

Letters to the Editor should not exceed 500 words.

"Geriatric Emergencies"

SIR,—I suggest that the difficulties in Dr. D. F. C. Deacon's area, and in some others, may be partly ones of communication (7 October, p. 53).

The term "geriatric" carries too many meanings. Some speakers mean any patient over 65, but most exclude surgical cases; some mean any chronic illness; others only chronic illness of the elderly; some think only of confused or incontinent patients, or patients with social difficulties, or possibly both. I fear that our administration will never be rid of this word, once coined to describe certain new medical knowledge, but now applied to beds, chairs, wards, doctors, and anything else in need of an adjective. May I plead for caution when recommending patients for admission? Ambiguity at such times can be disastrous.

"Geriatric emergencies" are not always medical emergencies. They may prove to have chronic dementia, longstanding hemiplegia, or simply no home. Some small crisis, domestic or medical, has exacerbated long-standing difficulties. Admitted in haste, they block precious beds for months, for the longstay unit, geared carefully to an assessed

waiting-list, cannot suddenly take them over. Small wonder that "acute" wards try to exclude them.

Chronic dementia is a particularly serious problem. I hold strongly that these cases should be nursed apart from fully sane patients of any age and that they are as unsuitable for the acute geriatric wards as for the acute medical wards. Dr. Deacon's patients evidently agree with me. Confusion or delirium due to acute illness seems, however, to be tolerated by sane patients, who see the necessity for urgent physical treatment of so sick a man. Differential diagnosis may be difficult, but the relevant history helps greatly, and the general practitioner may know this best. If we are to separate these cases it is not enough to hold special beds empty for psychogeriatric emergencies. We must direct the right cases to these beds, and need a clear diagnosis on the telephone. The phrase "I have a geriatric emergency case" is too vague. Please can we avoid it?—I am, etc.,

G. DALAWELL WALKER.

Anfield, Liverpool 6.

Anaemia in Elderly Housebound Patients

SIR,—A survey was made among patients over the age of 65 and known to be housebound in an N.H.S. practice situated two miles north of the centre of Birmingham during 1964.¹ Many of them had been visited regularly, or at intervals, during the previous two or three years. Fifteen patients in the sample lived alone and 31 lived with a relative; eight of the latter group were men and the rest were women. Results were obtained from 45 of the 46. The mean age of the whole group was 81 years. Where the patient had been treated for anaemia during the previous two years the level before treatment was the level included in the survey.

Of the whole group 41% had haemoglobin levels below 12.0 g./100 ml. They all had mean corpuscular haemoglobin concentration levels below 31% and were considered iron-deficient. Some of the patients were known to be taking aspirin or to have hiatus herniae and other conditions from which they might have bled, but no evidence of overt bleeding was encountered during the survey.²

At the same time as the elderly housebound were being examined a stratified random sample of the whole practice population was investigated.¹ In this random sample the men and women born in 1880 and 1890, and who were 74 and 84 years old at the time of the survey, showed an incidence of anaemia of 17%, a figure similar to those of French³ in Staffordshire and

Semmens⁴ in Yorkshire, but higher than that of Hobson's survey in Sheffield.⁵ This suggests that those who are housebound by age and infirmity are especially liable to become anaemic. Similar figures for the incidence of anaemia are found among entrants to old people's homes.

The fact that most of the housebound patients had been seen at intervals during the previous year supports the opinion that it is easy to overlook anaemia, especially in the elderly, if reliance is placed on clinical observation. This may be partly due to a stagnant peripheral circulation giving a false impression of health, and partly to an all-too-easy attribution of lassitude in the elderly to senile changes. Most general practitioners have a number of patients who are visited at intervals because they are known to be housebound. If the incidence of anaemia generally is as high as is suggested by the present survey then this section of the population warrants periodic checks by the general practitioner or health visitor so that the development of anaemia does not go unnoticed.—I am, etc.,

Cambridge.

Massive Overdose of Adrenaline

SIR,—I would like to comment on the case of adrenaline overdosage described by Dr. M. A. Lewis (7 October, p. 38).

The picture described is similar to, but more severe than, that seen in a phaeochromocytoma crisis. Initially, due to catecholamine release, there is intense vasoconstriction and hypertension. During this vasoconstrictive phase circulatory volume is depleted by loss of water, electrolytes, and plasma proteins into the tissue spaces. Following this phase, with return of more normal vascular tone, the patient may be found to be hypotensive, since he is by now hypovolaemic: the paradoxical hypotension of a phaeochromocytoma crisis. The use of vasopressors at this stage tends to prolong the vasoconstriction and prolong the hypovolaemia (? and hypotension). The adrenaline used may, by local vasoconstriction, have produced a "depot" anyway. Intravenous lactated Ringer solution, plus a longer-acting blocking agent such as phenoxybenzamine, is indicated here to convert the patient with a state reminiscent of acute peripheral circulatory failure with cold white skin to a warm, pink, vasodilated patient with adequate tissue perfusion and renal output.

It would be interesting to know whether haemoglobin estimations were done on the patient described. One would expect initial haemoconcentration, perhaps gross, with a gradual return to normal as the patient replenished a low circulatory volume.—I am, etc.,

M. C. CROCKER.

Department of Thoracic and
Cardiovascular Surgery,
Groby Road Hospital,
Leicester.

SIR,—Dr. M. A. Lewis is to be congratulated on successfully treating a patient who had received a subcutaneous injection of 16 mg. adrenaline by giving trimetaphan camsylate (7 October, p. 38).

He refers to my review of similar cases¹ in which I stated that the maximum tolerated dose of adrenaline was in the region of 7–8 mg. The patients who survived these doses had received no treatment and the figure of 7–8 mg. for the maximum tolerated dose accordingly still stands.—I am, etc.,

Dulwich Hospital, BERNARD J. FREEDMAN,

Bottle Cuts

SIR,—Over the past three weeks I have treated at least three severe lacerations—in these instances due to milk bottles, though no doubt beer bottles play an equally important part. The first involved the ulnar nerve in the arm, the second involved the radial nerve in the forearm, and the third involved the superficial palmar arterial arch in the hand. The arm and forearm lacerations also in-

volved the surrounding muscles, causing considerable damage. In each case an unfortunate milkman had slipped on a wet and slippery pavement or step and fallen heavily on a glass bottle, which had shattered and caused the injury. Altogether a total of about three hours was taken for treatment of these cases, the work involving up to three doctors at any one time, with a difficult exploration and nerve suture.

Our casualty department sees and treats between 80 and 120 new attendances daily from a large catchment area, including dock-yards and a motorway. There is one duty casualty officer, with orthopaedic and surgical firms on call, and a second casualty officer seeing reattendances for a few hours in the morning only, and such lacerations impose a severe strain, involving delay in treatment for many patients.

Prevention is always better than a cure, which often is incomplete in these cases. Little can be done about our English weather and wet slippery pavements, but surely in this age of plastics much time and expense would be saved to busy casualty departments and the public if milk distributors and brewers would supply their products in polyethylene bottles. Is there some objection to this or do these firms not realize the potential danger of their containers?—I am, etc.,

MALCOLM J. MCARTHUR.

Humidification of Oxygen

SIR,—Information supplied in the article "Is the Woulfe Bottle an Efficient Humidifier of Oxygen?" (29 July, p. 277) must not go uncriticized. The hair hygrometer is not constantly accurate over large ranges of humidity and if so used must be constantly recalibrated for the range in which it is being used. It is generally conceded that hygrometry gives constant and accurate results.

Method of delivery is not discussed, and this will determine the actual atmosphere inhaled by the patient. With nasal catheters there is a marked tendency for patients to breathe via the mouth, and this will negate somewhat the attempt at humidification, since mouth breathing will produce conditions in the trachea of 31° C. and 26 g./cu. m., much lower than those found when breathing via the nose (34° C. and 34 air humidity). The best results with this method, and these under the most unusual and artificial conditions, were 27.7 air humidity, still 5–12 below that found naturally, even in the oropharynx. The high levels of humidity reported do not obtain in practice. Even in Australia the average daily summer temperature is 22° C. with 12.9 air humidity. This does not take account of winter temperatures or cool nights, for oxygen therapy often must be continuous. One can assume that the gas issuing from the bottles is saturated with water vapour, and this certainly will be so with the modern diffuser. The statement that absolute humidity is dependent upon relative humidity and temperature is correct—not ambient temperature, but the temperature of the water bath. It is simple enough for anyone to fairly estimate the humidity being delivered, and this has been done using the information supplied in the text and the graph (Fig. 2) of the article.

Ambient temperature minus temperature drop in water below ambient equals temperature of water bath.

Flow l. per Minute	3	5	8
	g./cu. m.	g./cu. m.	g./cu. m.
Cool	6.5–7	5.5–6.5	6–6.5
Hot	22.9–26.9	18.9–22.9	16–20.0

These results are lower than that reported in the article and are those usually found in practice. The only worth-while results are those with low flows which will limit the application of the method, and these were obtained under unusual artificial conditions.

Without external heating this method at best prevents the inhalation of dry gas and does nothing to augment the humidification or produce high humidity which is required for some conditions—for example, tracheo-bronchitis; tracheostomy. The method is only indicated for oxygen therapy of short duration.—I am, etc.,

Respiratory Distress Syndrome

SIR,—Because the oesophagus enters the stomach from behind it is difficult to belch while lying on the back; and if Dr. Mark Reid's babies (30 September, p. 863) are nursed supine this may account for their distension after bicarbonate.

Over the past two years, for ill newborn babies, I have turned increasingly from intravenous treatment to immediate hourly tube feeds of 20% dextrose and 1–2% sodium bicarbonate, alternating with milk. Babies tolerate this well if kept throughout on their bellies in a head-up position.—I am, etc.,

Downton,
Wiltshire.

T. H. HUGHES-DAVIES.

Anxiety State after "Sex Education"

SIR,—Dr. Louise F. W. Eickhoff (30 September, p. 865) must have realized that her 10-year-old boy patient attending "the excellent boarding school" was psychologically vulnerable from an early age as he had no father to initiate him in the male role. Presumably one of the reasons for sending such a boy to boarding school was just this. Perhaps Dr. Eickhoff had something to do with this recommendation and now regrets it, for in many ways a child with family social problems is better able to work through these at home. Residential schools may be a socially and an educationally expedient way of side-stepping certain emotional situations.

As a school doctor for some years, I am now much more hesitant about this traditional middle-class way of putting such problems into cold-storage (possibly to occur later in life or in the next generation). Those interested in developmental paediatrics are fascinated by the phasing of the several biological

rhythms that exist, but every child has to face his or her puberty at some time. Some children are by instinct better orientated towards somatic and autonomic phenomena than others. Some have to be taught. Who better to teach than teachers? School doctors, health visitors, or school nurses perhaps.

It should not be our medical concern to avoid all anxiety in 10-year-olds. A certain amount of anxiety shows a healthy awareness of life. Rather it is its absence, or its unsatisfactory resolution, that is prejudicial to the future mental health of the child. Had the whole class shown anxiety one might think something had gone amiss.—I am, etc.,

Chesham Bois,
Amersham, Bucks.

B. H. BURNE.

Hospital Admissions among Students

SIR,—Dr. Graham Grant (9 September, p. 674) does well to publicize the fact that students do suffer from serious as well as trivial disease, and that between 2% and 3% of them have to be admitted to hospital each year. The figures for students at the University College of Swansea for the same years as he studied (1963–5) show the same incidence (182 admissions affecting 170 out of a total of 7,110 students). The proportion of women students was at least as high as Dr. Grant's—namely, between 25% and 30%.

However, Dr. Grant emphasizes the high proportion of admissions for mental, psychoneurotic, and personality disorders, and also for conditions associated with pregnancy—respectively 21% and 9% of the total admissions. This is not universally true, however, and the corresponding figures at Swansea are 9% and 4%. So far as I can see this is not due to under-reporting of admissions due to these conditions here, and I think it important that the general impression held by many people, both doctors and others, that these conditions are so common among students should not be encouraged by the publication of figures from only one university.—I am, etc.,

University College of
Swansea.

T. C. DANN.

Carcinogenic Properties of Ortho-dianisidine

SIR,—I refer to Dr. E. D. Acheson's letter (7 October, p. 51). It is true that Occultest and Hematest (Ames Company) contain ortho-tolidine as an indicator for occult blood. However, if these tablets are used in accordance with the manufacturer's instructions there is no risk whatsoever. Indeed, it would be more logical to indicate on packets of cigarettes that a noxious substance is contained therein.

I am most anxious that no taint of toxicity be attributed to such an excellent diagnostic method.—I am, etc.,

Edinburgh 10.

D. G. ILLINGWORTH.

SIR,—Carcinogenic aromatic amines have been used as chemical reagents in laboratories for many years (26 August, p. 557).

This Institute has drawn attention to the possible hazards from these in a pamphlet entitled "Precautions for Laboratory Workers

who Handle Carcinogenic Aromatic Amines."¹ Whereas a number of aromatic amines are known to induce cancer, no arylamino sulphonic acids have been found to be carcinogenic. There is no evidence that the sulphonic acid group is removed by metabolic processes.

In view of this it has been recommended that Cleve's acid (1-naphthylamine-7-sulphonic acid or 8-aminonaphthyl-2-sulphonic acid) should be used in the Griess-Ilosvay test for nitrite.^{2,3} The colours given in this test by 1-naphthylamine and Cleve's acid are similar, so that the same colour discs can be used in the estimations.—We are, etc.,

E. BOYLAND.

Melanoma, Halothane, and Liver Necrosis

SIR,—The letter by Mr. Geoffrey S. W. Organe and Dr. Gavin L. B. Thurston (7 October, p. 49) tends to give the impression that halothane is the only anaesthetic agent which, on repeated administration, may be followed by jaundice and liver necrosis. Such an impression would be misleading. It has been reported¹ that repeated administration of an intravenous barbiturate to 329 patients was followed by jaundice in 41 of them, 15 of whom died from liver necrosis. This unhappy event was investigated by medical officers responsible for the public health. After a careful study of all the relevant facts they concluded that the jaundice and the liver necrosis were caused by a virus transmitted during the intravenous injections.

It seems to me that the problem of unexpected postanaesthetic jaundice will not be solved until we provide ourselves with a reliable serological test for viral hepatitis.—I am, etc.,

Adenomyoma of Stomach

SIR,—Following the interesting description of gastric adenomyoma given by Dr. J. G. McNulty (30 September, p. 843), we would like to report a case in which the lesion was viewed through a gastric fibroscope and its appearance recorded by intragastric photographs.

A 42-year-old woman presented with an eight-weeks history of recurrent epigastric pain which was unrelated to meals and incompletely relieved by alkali. She had lost 8 lb. (3.6 kg.) in weight. Two years previously she had experienced similar symptoms, which then resolved after a few weeks. At the time of her referral to hospital a barium-meal examination showed an abnormality on the lesser curve of the stomach, adjacent to the angulus. Endoscopy was performed with a

fibrescope incorporating a gastric camera. A circumscribed lesion was identified in the proximal antrum, but it did not manifest the features of simple peptic ulceration. It comprised a raised smooth area with rounded edges and in the centre was umbilication or shallow ulceration. The findings did not allow a confident endoscopic diagnosis; a neoplasm was suspected and a Bilroth I partial gastrectomy was carried out.

The gastrectomy specimen contained a raised lesion 2 cu. mm. in diameter, with a central irregular umbilicated area situated close to the lesser curve near the angulus. Section showed a partly cystic ill-defined mass in the muscle coats and slender channels could be seen passing up from the cysts to open into the base of the umbilicated area. Histological examination revealed a typical adenomyoma with areas of well-marked pancreatic differentiation and cyst formation. The channels, passing up from the cysts, were lined by a tall columnar epithelium which was in direct continuity with the gastric mucosa. There was no evidence of ulceration or malignancy.—We are, etc.,

Operations on the Gall Bladder

SIR,—Your leading article (30 September, p. 811) is open to criticism. *The Registrar General's Statistical Review of 1962*¹ shows that if deaths from malignant disease of the biliary passages (Code No. 155a), from cholecystitis and cholangitis without mention of gallstones (Code No. 585), from cholelithiasis (584), and from other diseases of the gall bladder (586) are combined the death rates per million living are:

	At Ages 45-54	55-64
Males ...	17.5	61.5
Female ...	19	91

On the assumption that 5-10% of the population have gallstones by the age of 60, 50-100,000 operations per million will be needed to eliminate them; and besides disorganizing the N.H.S. these will give (at your suggested operation mortality of 1%) an increased mortality from gall-bladder disease of 500-1,000 per million. The "careful studies" which you quote as providing "factual information" seem to neglect clinical common-sense arithmetic.

It is more speculative, but fairer to your argument, to consider the equilibrium state when a policy of removing silent stones has been followed for some time. At present it looks as if about 750,000 persons out of the present annual total of births will survive to the age of 60. If every gallstone carrier is operated on by this age it will cost 400-700 premature deaths to make a clean start with a virtually gallstone-free population at this age. Unfortunately most gallstones develop after 60, and we cannot expect deaths from this cause at ages over 70 to be more than halved. In 1962 exactly 700 deaths were certified as due to cholelithiasis, 470 of them in patients over 70. This number will obviously increase as the elderly population increases (? to about 600). It is possible, therefore, that early operation would lessen the total number of deaths ascribed to various

forms of gall-bladder disease, but only at the cost of a lessened expectation of life.—I am, etc.,

Budleigh Salterton,
Devon.

DENYS JENNING.

Phenobarbitone and the Shoulder-Hand Syndrome

SIR,—Recently a woman of 35 years, upon whom we performed a stereotaxic thalamotomy for Parkinsonism with predominant rigidity, developed a contralateral shoulder-hand syndrome with oedema of the wrist on the fourth day after operation. Phenobarbitone was administered to her for the first time from the day of operation onwards in the dose of 30 mg. thrice daily. Within a few days she experienced similar pain, though to a lesser degree, in the opposite upper limb and both lower limbs. The pain was confined to the region of her joints but was not sufficient to restrict their mobility. She could not recall ever having suffered from such pains before or during the course of her illness, nor was she subject to epileptic seizures, thereby precluding shoulder trauma. Salicylates were tried for a few days, but proved ineffective. It was then that one of us recalled your leading article (15 April, 1967, p. 130) on the subject and phenobarbitone was discontinued, with the result that pain and oedema rapidly subsided. We are, etc.,

K.E.M. Hospital,
Parel, Bombay, India.

Aspirin and Gastric Bleeding

SIR,—The leading article on aspirin and gastric bleeding (30 September, p. 810) is on a timely subject but fails to present the broad and basic aspects of the problem. While aspirin may occasionally produce gastric haemorrhage by direct action on the gastric mucosa, it seems certain that this is not the *modus operandi* responsible for most of the occult gastrointestinal bleeding nor for the massive haemorrhages. As I have recently pointed out, aspirin causes occult bleeding to varying degrees even in normal subjects,¹ whereas sodium salicylate does not. Obviously, aspirin induces haemorrhage by virtue of its acetyl linkage.

Without going into theoretical considerations, two practical facts concerning aspirin should be stressed. Certain normal subjects and many with a bleeding tendency, particularly those with the Minot/von Willebrand syndrome, will have a prolonged bleeding time after ingesting a small dose of aspirin and occasionally have an accentuation of their bleeding tendency. By means of the aspirin tolerance test such subjects can readily be detected.

The second cogent fact, which is often overlooked, is that aspirin has two pharmacological activities: through its acetyl group it is an effective analgesic, and through its salicylate content it is an anti-inflammatory agent. It is the latter action that explains

its therapeutic effectiveness in rheumatic fever and rheumatoid arthritis. In these conditions a high concentration of salicylate in the blood must be maintained. This can be accomplished by either sodium salicylate or aspirin. The latter is completely hydrolysed in a few hours after ingestion, and thus furnishes salicylate ions. There is no evidence that aspirin itself has any anti-inflammatory action. Since large doses of aspirin may induce gastrointestinal bleeding, even in patients with no evidence of a bleeding disease, it seems logical to use sodium salicylate to maintain a high level of salicylate in the blood. Recent studies in my laboratory indicate that this drug, unlike aspirin, does not cause the diapedetic or mucous membrane bleeding.—I am, etc.,

Children with Myelomeningocele

SIR,—As an offshoot of our research into the assessment of gait in cerebral palsied children we designed a hip level "polyplanar" joint for use with callipers of the type described in Mr. E. H. Strach's article (23 September, p. 791). Our object was to reproduce a walking pattern as near normal as possible. The joint illustrated (Fig. 1) ensures external rotation with hip flexion and internal rotation with extension which gives pelvic rotation, thus allowing normal weight transference on to the forward leg.¹

By interconnecting the two joints on either side stability can be gained without the loss of mobility, since only reciprocal hip movements are possible. We have used inflatable splints for stabilizing the limbs of children with cerebral palsy,² and we first fitted a pneumatic system to the callipers, accepting that a more expensive hydraulic system would give less "back lash." Now we are trying a cheap twin cable system which can be preloaded to take up all excess movement (Fig.

2). Although it is still in the development stage, we have been encouraged by the remark of a parent, who said (of his child with myelomeningocele), on seeing the callipers in use, "But this is ordinary walking!"

FIG. 2

Recent engineering advances have influenced other appliances, but the humble calliper has, through its dependability, ceased to evolve. The resultant gait is accepted as inevitable—but need it really be so? Perhaps the motor problems of the child with a myelomeningocele will form the environmental background for the next evolutionary stage of the full-length calliper.—We are, etc.,

SIR,—In Mr. E. H. Strach's very interesting and comprehensive article on myelomeningocele (23 September, p. 791) he does me the honour to recommend for hip complications my simple splint, originally designed for congenital hip dislocations in infants, which was widely popularized in Europe (unfortunately excluding Britain) and in South America by Professor Putti, the pioneer of early diagnosis of congenital dislocation of the hip. I am tempted to recommend another simple apparatus for the early treatment of meningocele when conditions do not permit radical operation immediately after birth, which gives such good results in the hands of highly skilled surgeons, and for which some cases have no access or are unfit.

What I refer to is a protective dome of perspex, or other plastic, well perforated to allow evaporation and large enough to avoid all contact with the surface of the swelling, but supported by a flange resting on the normal surrounding skin and held in place by tapes round the axillae and groins. The surface of the swelling is dusted with an inert powder and no dressing applied. If the child is very small the perspex may be shaped as a cylinder along the whole spine.

During my years working in the Bath and Wessex area I had many opportunities of using this method, though not a series comparable with Mr. Strach's large one. It was surprising how, within a few days, the tumour steadily shrank and normal skin grew in over the remainder from the edges. A few cases died suddenly and unexpectedly within a matter of days, or weeks, probably from cerebral complications, but those that survived had no degree of paraplegia, nor lack of sphincter control.

Many unfortunate cases reached me who had had a belated excision, before the modern technique had developed, and they uniformly had paraplegia with incontinence of bowel and bladder, and provided difficult problems to get them ambulatory.—I am, etc.,

Edinburgh.

M. FORRESTER-BROWN.

Psychotropic Drugs

SIR,—I would be grateful for the opportunity to add my comments on the Dunlop Committee's report on psychotropic drugs.¹

The immediate and obvious conclusion is the remarkable safety of these drugs. Taking the general-practice figures only, the adverse reactions approximate to something like 0.003% of each prescription, and the fatal reactions to one-fourteenth of this figure. There is no doubt that these drugs have transformed psychiatric treatment and relieved much suffering in both psychotic and neurotic illnesses. Contrary to the widely held lay belief that psychiatric patients become dependent on these drugs, the general experience is that most of them tend to stop the drugs too early, as soon as they feel better. It is therefore all the more unfortunate that such wide publicity should be given in the press to the Dunlop Committee's report. Already several of my patients, not appreciating the remarkably small number of adverse reactions, have expressed anxieties about being on psychotropic drugs, and a few actually stopped them for a time.

The Committee's reports are most helpful to the doctor in advising him of possible adverse reactions to any drug, but I cannot see that the wide promulgation of its findings and suggestions in the press can have any value to the general public, and can only promote anxiety in any patient who should happen to be on that drug.

I would therefore make a strong plea that consideration should be given to distributing future reports of the Dunlop Committee on a strictly confidential basis to doctors only.—I am, etc.,

Stress Incontinence

SIR,—I was very interested in the correspondence from Mr. T. Moore (16 September, p. 740) and Mr. S. A. Vincent (19 August, p. 498) about the treatment of stress incontinence by electrical stimulation.

In this unit we have for some years been treating such patients by "maximal" electrical stimulation, but using this term time-rather than current-wise. We have been treating them with an implant with the electrodes placed on the anterior fibres of the levator, the implant being activated by a radio-frequency linkage through the small external unit worn by the patient. We have observed a "lift forward" of the bladder neck on stimulation, and this fits in well with the theories of continence put forward by Jeffcoate and the Liverpool school.¹ We have found that sometimes stimulation gives rise to an increased urethral pressure, but sometimes this is not observed.

The advantage of this treatment is that although the patient has a small operation she does not then need to attend the physiotherapy or other department except for routine checks on her equipment. The patient will notice a deterioration of the equipment because she becomes wet. This work was described in my Hunterian lecture (December 1966; to be published), although since then improvements in technique have been developed.

In two cases we have used "Hopkinson's plug"² successfully. In one case because there had been so many retro-pubic interventions that it was impossible to use this approach again, and in the second case because it was felt that the patient was too senile for an operation.—I am, etc.,

K. P. S. CALDWELL.

SIR,—Having read in your correspondence columns of the interesting results achieved by Mr. S. A. Vincent (19 August, p. 498) and by Mr. T. Moore (16 September, p. 740) by electrical stimulation of the perineal muscles, I beg to state that I cured one young woman who was sorely afflicted by ordering her to take riding lessons.

Before this is dismissed as a successful case of psychotherapy I should like to make two points:

(1) That she informed me that during the first few rides her saddle became soaking wet, and that over a period of weeks she got progressively drier and finally achieved complete control.

(2) That anyone who has attempted to remain in the saddle on an excitable animal by gripping with the knees and who has never ridden before, or not for many years, will know next day from their aching perineal and adductor muscles that every available fibre has been brought into vigorous action out of sheer terror.

This approach has a very limited application, but I have put it forward as I believe it might help in suitable cases.—I am, etc.,

York. J. K. WILLSON-PEPPER

Early Discharge of Maternity Patients

SIR,—May we reply to comments made on our papers (26 August, pp. 517 and 520).

We would endorse the view expressed by Dr. S. E. Browne (16 September, p. 739) and agree that the penultimate paragraph of the discussion of our second paper might have been more explicit. Although we agree in principle that children should be allowed to visit their mothers in maternity units, we submit that the facilities are inadequate to permit this in many units, including our own. We feel that Dr. R. S. Saxton's problem (16 September, p. 739) should receive sympathetic consideration by his local maternity liaison committee.

While agreeing with Dr. E. D. McEwan (23 September, p. 801) that the results of our survey agree with those mentioned in his most interesting paper,¹ of which we were aware, we wish to comment on two points. Firstly, only 101 of the 1,044 babies in his series were discharged within 72 hours of birth. We consider this a small sample from which to draw firm conclusions regarding the safety of discharging babies so early. Secondly, since in Bradford the breast-feeding habits of immigrants appear to be influenced by the length of their stay in this country, only European mothers were included in the breast-feeding survey. We regret this point was not clarified in our first paper.—We are, etc.,

Carpal Tunnel Syndrome Associated with a Scribner Shunt

SIR,—Various symptoms and signs resulting from median nerve compression at the wrist have been described.¹⁻⁵ This is a report of the carpal tunnel syndrome complicating an arteriovenous Teflon-silastic shunt⁶ at the wrist of a patient in terminal renal failure.

A 40-year-old patient with a 17-year history of recurrent pyelonephritis associated with bladder-neck obstruction was admitted in terminal renal failure for haemodialysis and ultimately renal transplantation. No clinical evidence of peripheral neuropathy was found.

A Teflon-silastic arteriovenous shunt was implanted in the left forearm near the wrist. The left radial artery and cephalic vein were cannulated under 1% lignocaine local anaesthesia. After four weeks, owing to recurrent clotting, this shunt had to be removed and another implanted in the right forearm. A week later the patient complained of numbness and tingling in the thumb, forefinger, and middle finger of the left hand, and weakness was noted in the left abductor pollicis brevis. No symptoms were present in the right hand. Three weeks later wasting became visible on the lateral border of the left thenar eminence, and paraesthesiae continued. There was also diminution in appreciation of light, and painful sensation over the left thumb, forefinger, and lateral half of the middle finger, and percussion over the flexor aspect of the left wrist stimulated paraesthesiae in the fingers already mentioned. At no time was the patient in heart failure, and x-rays of the wrist were normal.

Damage to the median nerve at the wrist incurred by the implantation or removal of a Scribner shunt has not hitherto been described. It seems unlikely that injury to the nerve occurred during the insertion of the shunt. It may, however, be accounted for by one of the following explanations:

Ligation of the distal end of the radial artery may have jeopardized the blood supply to the digital vessels and median nerve.

During the time that the curved portion of the arterial shunt lay in the subcutaneous tissues of the flexor aspect of the forearm pressure on the flexor retinaculum and median nerve may have resulted. Damage to the median nerve may have occurred as a result of direct pressure or by occlusion of the vasa nervorum.

During the removal of the clotted shunt trauma to the nerve or to its blood supply may have resulted from the measures taken to secure haemostasis.

I am grateful to Professor R. Y. Calne for permission to publish this case.

Sodium Chlorate Poisoning

SIR,—We agree with Dr. A. C. Kennedy and Dr. R. G. Luke (23 September, p. 801) that the incidence of acute renal failure due to chlorate ingestion is much greater than the reported cases would indicate. We must apologize for having failed to notice their patients, but a more serious omission is the paper of Jackson, Elder, and McDonnell,¹ which deals entirely with the subject of acute renal failure and chlorate poisoning illustrated by three cases.

For the review of the recent literature we relied on the very comprehensive review of "The Clinical Dialysis of Poisons" in the *Transactions of the American Society for Artificial Internal Organs*.² This check list has been MEDLARS assisted since 1963 but is clearly deficient before this date.—We are, etc.,

Headlight Glare

SIR,—The case of polarization to eliminate dazzle as suggested by Dr. S. J. Lines (30 September, p. 867) has been considered impracticable because cambering, banking, and surface irregularities of roads prevent 90° cross-polarization from being maintained.

The headlamps of an approaching vehicle would thus fluctuate in apparent brilliance.

The dazzle problem is admittedly serious, particularly in this country, where every motorist feels free to express his personality by festooning his car with extra lamps and other decorations. The position could be materially improved by enforcement of the Vehicle Lighting Regulations.

A dangerous and illegal practice which seems to be growing is the use of rear-mounted spotlamps to dazzle motorists behind. In one recent case known to me the victim was first harassed by close pursuit with undipped headlamps, then passed and blinded by the rear-spots until the aggressor became bored and disappeared into the night. The circumstances prevent the victim from reading the registration number of the offending vehicle, but prevention should be simple—in daylight the illegal lamps can be seen just as easily by the police and traffic wardens as by anyone else.—I am, etc.,

University of Glasgow.

N. R. GRIST.

Fluoridation of Water Supplies

SIR,—Fluoridation of water supplies is official B.M.A. policy, and one gathers that the Ministry of Health is trying to persuade local authorities to put this policy into effect.

One also gathers that as time goes by increasing numbers of eminent doctors and scientists, too numerous to list here, are coming to have grave doubts about the wisdom of this policy. Few who study the case against fluoridation (and most do not) can also fail to have grave doubts. Surely it is time that the whole question of fluoridation of water supplies was reassessed.

Fluoridation has been practised in parts of the United States for some years, and there is evidence that fluoridation postpones but does not prevent the onset of caries,^{1,2} and that when caries does come conservative dentistry is rendered more difficult.³⁻⁵ There is also evidence that fluoridation is definitely harmful to a proportion of the population, particularly those with damaged kidneys, and that others become allergic to it.⁶⁻⁸ Even if the percentage of these people is small, no one has the right to poison them through the public water supply. (It is not everyone who can dig a well in the back yard, as the lady in Andover had to do in 1956 when Andover fluoridated its water.)

In fluoridating water supplies the dose to the individual cannot be regulated. Fluoride may be put into the water supply at 1 p.p.m. but does not necessarily get evenly distributed, and samples have been found to vary from 0.4 to 1.4 p.p.m. (for example, in Wilmingtan, Mass.). And of course some drink more water than others. The undiagnosed diabetic and those whose job makes them perspire freely may drink as much as 30 pints (17 l.) a day; this gives an intake of 17 mg. of fluoride, which, with 2 or 3 more from other foods such as tea and fish, brings it up to the chronic toxic dose of 20 mg.

Fluoridation of public water supplies amounts to compulsory mass medication and is morally quite unjustifiable. It infringes human freedom—the freedom of a doctor to treat his patients as he thinks best, and the freedom of the patient to choose whether to accept or reject the medication advised. Any doctor can now treat his young patients with

fluoride if he thinks it desirable. And every child can have it in accurate dosage if his doctors and parents wish it, but there is no need to force the rest of the population to ingest a toxic substance every day of their lives in uncontrollable doses, knowing that it will quite certainly harm some people, and having no idea whatever what the effect will be on the rest.

Anyway the proper way to control dental caries is to educate women not to stuff their children with sweets, white sugar, and sweet biscuits, and to see that they clean their teeth after meals.—I am, etc.,

Peaslake, Surrey.

Mortality of Bereavement

SIR,—It is always refreshing to see someone take up a popular belief and put it to the test of science. Dr. W. D. Rees and Miss Sylvia G. Lutkins (7 October, p. 13) have presented a well-documented study of the mortality of bereavement. To illustrate their statistical material a case report might be in point.

Some time ago I had occasion to treat an old childless couple over a period of five years. Two other specialists were also involved in the care of these patients, whom we got to know

very well. Champion tennis players and hole-in-one golfers, the devoted couple kept active, doing everything jointly, and invariably came to the surgery together. It is significant that each time any of the three doctors exchanged opinion about the couple the feeling was expressed that if one spouse died the other would follow very soon. Admitted as an emergency to hospital, the woman died of peritonitis from perforated diverticulitis. Three months after his bereavement the widower died of acute coronary occlusion, while heart disease had not till then been a major complaint.

Those with close feelings toward canine friends take it as a fact that dogs can die of a broken heart. Indeed, recent references show that this term might not be out of place after all. Perhaps research on the above laboratory animal could answer some of the questions regarding the pathology of grief raised in your leading article.—I am, etc.,

Denens,
Switzerland.

S. W. A. GUNN.

Intestinal Spirochaetosis

SIR,—In reference to the communication by Dr. W. A. Harland and Dr. F. D. Lee on this subject (16 September, p. 718) I feel it should be recalled that in the early 1950s Dr. A. G. Shera, then pathologist to the Eastbourne Hospital, presented to a meeting of the Association of Clinical Pathologists a description of this condition fully illustrated by microscopical preparations and with clinical details of several cases. A précis of Dr. Shera's presentation appeared in the *Journal of Clinical Pathology*.¹

It has always been my opinion that Dr. Shera's observations failed to attract the attention they deserved.—I am, etc.,

Wolverhampton,
Staffs.

Approval of Emergency Treatment Service

SIR,—The reported statement of the chairman of the Inner London Executive Council (*Supplement*, 7 October, p. 3) that his council was not to blame for the temporary abandonment of the British Medical Association Emergency Treatment Service in London is interesting. The Inner London Executive Council has never been so blamed, the suggestion in the letter sent to London doctors being that the slow response from practitioners there might partly be due to the long delay in giving approval to the service. And, whatever the reason for the chairman's hastening to don this particular cap, there can be no argument that a period of some nine months' waiting could fairly be described as a delay, a delay in this case in the provision of a service to patients which could only have been of considerable benefit to them—an aspect which has apparently been quietly ignored in all this time except perhaps by one national newspaper.

But the reasons given by the chairman for this delay are even more interesting, not to say alarming. The council, though "satisfied that the service sponsored by the B.M.A. would be of high quality," concerned itself with other matters, "in the interests of the doctors who would use the service"—in short, with the company structure, which was being changed, of the operating company,

with a booklet issued by the B.M.A., and with the contract forms, in use throughout the country, to be used by subscribing doctors wishing to join the service. These forms were found to be quite unacceptable—by the executive council, need I say. Obviously doctors who had already signed these contracts had not found them so.

Sir, it would seem to me that it is time that all members of the executive council, and particularly the relevant subcommittees, should read the E.C.N.s 415 and 573 and the E.C.L. 103/66 and learn or remind themselves of the instructions and guidance on deputizing services offered therein by the Minister.

It is the duty of an executive council to give permission to an individual doctor to use a deputizing service, to refuse this permission, or to modify or qualify his use of such a service, and to do so the council must obviously have first-hand knowledge of the efficiency and method of working of the service. The council freely admitted the high quality of the B.M.A.-sponsored deputizing scheme, which is the limit of its remit so far as the organization as opposed to the individual practitioner is concerned.

Nowhere have I seen a suggestion that an executive council should concern itself with the private contractual arrangements of a

Senokot restores natural rhythm to the constipated colon

Senokot, standardized senna, has earned a reputation for effectiveness and safety. Over 150 references in medical journals and text books testify to its value. Senokot is suitable for all ages and is useful in pregnancy and in geriatric cases. It is predictable in its action and, taken in the correct dosage, is free from griping. Acting specifically in the colon, it induces controlled peristaltic action and restores the normal defaecation reflex leading to re-education of the bowel.

BASIC NHS COST: From the dispensing packs, the cost of a teaspoonful of granules or two tablets is about a halfpenny.

Granules: 56, 170 and 900 grammes.

Tablets: 50, 100, 200, 1000.

SENOKOT

STANDARDIZED SENNA

re-educates the bowel

Westminster Laboratories Limited,
Dansom Lane, Hull, Yorkshire.

general practitioner unless there is a possibility of a breach of the regulations. Nowhere have I seen it suggested that an executive council should concern itself with literature issued by the B.M.A.—God forbid! Nowhere have I seen a suggestion that an executive council should concern itself with the internal intricacies of company formation once the efficiency of the organization has been established.

Whether inspired by fatherly interest or big-brotherly determination, executive councils must be sharply reminded that their interference in contractual or other arrangements made by general practitioners with other parties, and in the absence of any breach of the regulations, will be deeply resented and utterly repudiated, not only by the individual doctors who have their liberty of action once again questioned, but by the B.M.A., G.P.A., M.P.U., and any other professional organization.

Finally, I would recommend to the Inner London Executive Council a long, cool look at their own "contracts" with general practitioners, unilaterally signed, in the hope that it might stimulate some thought on the standing, the legality, the value, and the fairness of this piece of paper which every practitioner must sign when joining an executive council list as a principal.—I am, etc.,

Sheffield.

W. P. LAMBIE.

Dependent Relatives

SIR,—There will be many who were surprised by Dr. A. Youatt's letter (30 September, p. 868). I myself am not wholly able to follow the last part of his argument about "tax having been paid" on his estimated collective value of relatives' services. But the one incontrovertible fact which emerges is that he has paid, and has had accepted by his local tax inspector, the charge for the services of a dependent relative as a secretary/receptionist in his practice at a figure of £1,200 per annum. This may sound a startling sum to some doctors. However, this is no surprise to me.

In 1963 I took an appeal to the Special Commissioners over the vexed question of charges for the services of dependent relatives. At that time my wife was responsible for secretarial duties, largely at week-ends and in the evenings. For these services the Commissioners agreed that a sum of £520 per annum (plus £120 for her relief during sickness) was commercially justified on the facts. Clearly, on this basis, any dependent relatives who are giving services, as many do 24 hours a day, seven days a week, will be worth commercially upwards of twice this amount; particularly if, as is frequently the case, they possess qualifications making them specially suitable for the services given.

Following this appeal it became apparent to me that, if this pattern were to be followed by all G.P.s, it would have a profound effect on their own gross remuneration, which was then governed by the "Pool" system; this itself was determined in part by a Government sampling of tax returns. The position today is different in some respects. But the Review Body is dependent for guidance in pricing gross remuneration on similar tax sampling. Therefore, if all general practitioners were to show similarly realistic

though widely differing sums for the services of their relatives (where relevant), this would be reflected in the gross remuneration paid to general practitioners in respect of overheads or running costs of their practices.

In order, however, to justify proper charges for the services of related staff certain requirements have to be fulfilled:

(a) The facts in each individual case must be established, preferably using a standard fact-finding technique.

(b) The valuation of the services should be the result of the application of standard objective criteria to the established facts.

(c) There should be clear evidence that the related supplier of the services on the one hand and the doctor to whom they are being supplied on the other hand have put such services on a formal contractual basis.

(d) That there is proof that services have actually been paid for.

It will be seen from this that doctors may experience some difficulty (as I did) in establishing that the changes have been valued on an objective commercial basis rather than on a purely subjective one decided upon between the doctor and the related staff, with little or no relation to their commercial worth. It was for this reason that I formed a company, Medical Management Services Ltd. The company commissioned a leading firm of management consultants to conduct a "job specification and evaluation" for certain administrative services common to most practices. As a result M.M.S. Ltd. has evolved, with the firm of chartered accountants who administer it, its own method of evaluation for ancillary services. This has proved acceptable to the Revenue in actual practice in widely separated parts of the country.

The object of this is not to save tax—any tax saving is incidental—but to demonstrate incontrovertibly the realistic cost of running a medical practice.—I am, etc.,

Poole, Dorset.

G. C. PRICE.

Vocational Training for General Practice

SIR,—In the *Supplement* of 23 September (p. 135) you report Mr. D. C. Bowie as saying, "If young men and women were trained in scientific medicine it would be a waste and a failure if they could not practise that kind of medicine. Therefore it was very important that conditions should be created in general practice in which young graduates could continue in the way in which they had been trained." I cannot believe that you have correctly reported my old friend Mr. Bowie in making him put forward a proposition which is really declaring that, instead of doctors being trained to treat the complaints which patients present, patients in general practice should be trained to present the complaints which doctors are capable of treating.

Surely one of the greatest troubles in general practice is that doctors have been trained in hospital by people who know nothing about general practice and are therefore quite incapable of teaching it. The way to stop the "waste" is to have less training in the so-called "scientific" medicine, and more encouragement for general intelligence and humanity.—I am, etc.,

Newick, Sussex.

F. GRAY.

Mileage Allowances

SIR,—We now see the results of the long-awaited interim mileage allowances negotiated between the B.M.A. and the Ministry (19 August, *Supplement*, p. 121). A reduction of 3d. a mile for cars under 1200. This new system excludes all cars in the popular range, which previously qualified as over 10 h.p.—for example, Cortina, Anglia, Viva, Morris 1000, and 1100.

It is obvious that those who can ill afford it are being penalized at the expense of their richer colleagues. No wonder the junior medical staff have no faith in the B.M.A., and why large numbers of senior medical staff see no reason for returning to the fold.—I am, etc.,

Stoke Poges, Bucks.

D. L. BENNETT.

SIR,—Concerning the recent change in mileage allowances, it appears that in fact anyone now acquiring a car of 1000–1199 c.c. capacity will qualify for a smaller allowance than before. As most popular small cars are of this size, the saving to the Health Service must be almost as much as the increase for other cars. Has it suddenly become less expensive to run a car of this size? Surely the willingness of doctors and dentists to use their cars on official business at a substantial loss is being sorely tried by this change.—I am, etc.,

Eaton, Norwich.

R. J. PURNELL.

Post-registration Nurses

SIR,—I find it rather incredible that Dr. A. Paton should refer to the post-registration nurse as "a relatively new educational phenomenon" (23 September, p. 788). Perhaps he is unaware that as far back as 1918 the Royal College of Nursing was holding a course for sister tutors and in 1921 held an international students' course in collaboration with Bedford College, London.

During the last few decades there has been a worldwide increase in the number and variety of courses offered to those who have completed their training. This is so not only in the professional world but also in the business world, which frequently is ahead of the professions in their vision of future needs.—I am, etc.,

Wimbledon,
London S.W.19.

MARGARET F. YOUNG.

Points from Letters

Safer Dental Anaesthesia

Mr. S. L. DRUMMOND-JACKSON (London W.1) writes: Few who have studied the subject deny that it is the "milling anaesthetic practice" run by those who would be least likely to take post-graduate instruction which is the best candidate for the highest proportion of anaesthetic hazards. No legislation can improve safety until the measures by which safer practice can be achieved are freely available. These measures, let us hope, will progressively increase, but they will start with courses of but a few days, whether we like it or not, and it will be at least ten years before we can reasonably expect that every man who administers an anaesthetic should have taken some form of approved instruction within the last x years. This may be restrictive, but so are many safety rules, and there are few alternatives which seem possible.

Obituary Notices

Sir ARCHIBALD GRAY, K.C.V.O., C.B.E., T.D., LL.D., M.D., F.R.C.P., F.R.C.S.

Sir Archibald Gray, consulting physician for diseases of the skin to University College Hospital and to the Hospital for Sick Children, Great Ormond Street, died at his home in London on 13 October. He was 87.

Not many men attain eminence in two fields as different as a specialized branch of medicine on the one hand and hospital and university administration on the other, but

[Bassano & Vandy]

Sir Archibald Gray was distinguished in both. For as long as 37 years he had charge of the skin department of University College Hospital, and there and elsewhere he built up a reputation which made his name familiar in dermatological circles all over the world. His gifts in the field of academic administration were evidenced in the succession of posts he held, up to that of Deputy Vice-Chancellor of the University of London.

Archibald Montague Henry Gray was born on 1 February 1880 at Ottery St. Mary, South Devon, the son of a general practitioner. He was educated at Cheltenham College, and he entered University College and Hospital, London. He also later studied in the University of Berne. He took the M.B. London with honours in 1903, and the B.S., again with honours, the following year. He proceeded M.D., with the University Medal, in 1905, took the F.R.C.S. in 1908, was elected F.R.C.P. in 1918, and was appointed C.B.E. the following year. During the first world war he was attached to the general staff at the War Office and was consulting dermatologist in the Army Zone, British Expeditionary Force, holding the rank of lieutenant-colonel, R.A.M.C. (T.A.). After the war he returned to a full life of activity in Gower Street, where he was physician to the skin department and lecturer in dermatology to the medical school. He had charge also of the skin department at the Great Ormond Street Hospital for Sick Children from 1920 to 1924, and was consulting dermatologist for many years to the Royal Air Force and adviser in dermatology to the Ministry of Health and to the L.C.C. special hospitals.

Gray early began to take an interest in university affairs. He was a member of the Senate of the University of London from 1929 to 1950, a member of the Court from 1947 to 1958, and Deputy Vice-Chancellor in 1938-9. In his own school he was Dean from 1926 to 1935, and Dean of the Faculty of Medicine of London University from 1932 to 1936. He also represented his university on the General Medical Council. He was an excellent committee man and was made a member of the Government committee on the

medical services of the Navy, Army, and Air Force, which sat from 1931 to 1933, and of the inter-departmental committee on the organization of medical schools (better known as the Goodenough Committee), which sat from 1942 to 1944. In the Royal Society of Medicine he was a prominent figure. For many years he was a member of the Council of the Section of Dermatology and became its president. From 1919 to 1924 he was honorary secretary of the society, its honorary treasurer from 1926 to 1932, and in the difficult early years of the second world war its president.

In 1941 the Ministry of Health instituted a survey of hospital services, dividing England and Wales into 10 areas for the purpose, and appointing persons experienced in the clinical and administrative work of hospitals as surveying officers. Each report made a Blue Book and the whole was a kind of hospital Domesday. Sir Archibald Gray was responsible with Dr. Andrew Topping for the information relating to hospital services in London and the surrounding area. He had been before the war vice-chairman of the London Voluntary Hospitals Committee.

Sir Archibald Gray's achievements in the field of dermatology were widely recognized. His work was characterized by the scrupulous attention to detail demanded by the dermatologist, and by prolonged and careful study of the problem presented by the individual case. So long ago as 1913 he was chosen as honorary secretary of the Section of Dermatology at the 17th International Congress of Medicine in that year. He was vice-president of the International Congress of Dermatology in 1930 and its president in 1952. He was president of the British Association of Dermatology and Syphilology in 1938-9, honorary member of the Polish Academy of Science and Letters, the American Dermatological Association, the Spanish Academy of Dermatology, the Austrian Dermatological Society, and the Australian Dermatological Association, and he was corresponding member of the dermatological societies of France, Denmark, and Hungary. From 1948 to 1962 he was adviser in dermatology to the Ministry of Health, and from 1951 to 1961 chairman of the board of management of the London School of Hygiene and Tropical Medicine. He was knighted in 1946 and appointed K.C.V.O. in 1959. The honorary degree of LL.D. was conferred on him in 1958 by the University of London.

As Harveian Orator to the Royal College of Physicians in 1951 he gave a learned discourse on the history of dermatology since the time of Harvey, and ended by pointing out some of the problems remaining to be solved in the dermatological field, reminding his audience that the skin might respond to conditions affecting the organism as a whole or might act as an entirely independent organ, producing in itself its own toxins which might affect any part of the skin and leave the rest unaffected. He

was editor for some years of the *British Journal of Dermatology and Syphilology*, and author of the section on skin diseases in Price's *Textbook of the Practice of Medicine* and of articles on the subject in the *Medical Annual* and in the *Official Medical History of the [First World] War*.

In 1919 he married Elsie, daughter of the late Mr. F. B. Cooper, of Newcastle-under-Lyme, and they had one son and one daughter.

W. N. G. writes: It is just 45 years ago that I presented myself to Sir Archibald Gray (as he was to become) and was accepted as his clinical assistant at University College Hospital. Thenceforth he was my unfailing counsellor, friend, and supporter. Professionally I owe almost everything to him. The breadth of his knowledge and the exactness of his observation made his teaching lucid and convincing, and he had an almost photographic memory of clinical cases. Influence and power came to him naturally because of his exceptional competence and his interest in professional politics and college and university affairs. He did not seek the limelight, but did enjoy holding the reins of government. When he spoke in public it was with an authority that compelled attention, and this was aided by his splendidly clear voice and enunciation.

Sir Archibald arrived at his conclusions logically, and held his opinions so strongly that he could be impatient at times with those who had other views. But differences were always amicably composed, and he never harboured any rancour, and was essentially friendly. His friendships indeed were worldwide, and one of his proudest achievements was the organizing, under his presidency in London, of the first International Dermatological Congress to be held after the second world war. It was a most successful and happy event. For a man with such an active mind, vividly interested in all that was going on, his long incapacitating illness must have been a grievous trial. But it was always a pleasure to visit him, and one came away inspired by his cheerfulness, patience, and courage. He was happy and fortunate in his family circle, and drew great satisfaction from the attainments of his son, Professor John Gray, and from having a grandson a medical student at University College Hospital. To all his family I express my sympathy in their great loss, and especially to Lady Gray, who tended him so devotedly. I shall always remember Sir Archibald Gray with gratitude and affection.

A. G. TIMBRELL FISHER, M.C.
M.B., CH.B., F.R.C.S., F.A.C.S.

Mr. A. G. Timbrell Fisher, a former orthopaedic specialist at the Rheumatism Unit, St. Stephen's Hospital, and the Charterhouse Rheumatism Clinic, died on 10 October. He was 79.

Alfred George Timbrell Fisher, second son of Canon W. H. Fisher, was born in Bristol on 1 November 1887. He was edu-

cated at Clifton College, Bristol, and at Bristol University and St. Bartholomew's Hospital, London, qualifying with the Conjoint diploma in 1911 and graduating M.B., Ch.B. a year later. After early resident posts at the General Hospital, Bristol, he became demonstrator of anatomy, and of surgical applied anatomy, at Bristol University. During the first world war he served in France and Belgium as a surgical specialist with the R.A.M.C. and was awarded the

L. SURZYNSKI

Military Cross and mentioned in dispatches. After demobilization with the rank of major he took the F.R.C.S. in 1919, later holding the appointments of assistant surgeon in the orthopaedic department of St. Bartholomew's Hospital and in the surgical unit of University College Hospital. He was appointed surgeon in charge of out-patients at the Dreadnought Seamen's Hospital, Greenwich, and consulting surgeon to the Ministry of Pensions. In 1919-20, and again in 1921-2, he was Hunterian professor of the Royal College of Surgeons of England. A member of the British Medical Association, he was vice-president of the Section of Orthopaedics at the Annual Meeting in 1936. In 1948 he became a Fellow of the American College of Surgeons; he was also a Commander of the Order of St. John of Jerusalem. He was consulting surgeon to the St. John Clinic and Institute of Physical Medicine, and until he reached the age of retirement was orthopaedic surgeon to the Rheumatic Unit, St. Stephen's Hospital, Chelsea. He continued his work as a medical member of the medical and pensions appeal tribunal.

His books included *Internal Derangements of the Knee-Joint*, and *Treatment by Manipulation*, both of which went through several editions.

F.B. writes: Timbrell Fisher was a member of the *ad hoc* committee nominated by Lord Dawson of Penn to discuss the proposed terms of reference for the British committee on chronic rheumatic diseases which was to be appointed by the Royal College of Physicians. On its creation he was elected a member of both the subcommittee on classification and nomenclature and the editorial and literature subcommittee, to both of which he gave valuable service. His ideas were original; he marshalled his facts and wrote them down in clear and simple English. He based his writings on his careful pathological studies and his very successful treatment by manipulation in addition to the more orthodox orthopaedic measures practised at that time.

Timbrell Fisher was one who not only realized the importance of integration and communication to the proper study of the rheumatic diseases but what is even more important the need to apply what was being learned to the treatment not only of the individual patient who came under his care but to the management of all those who

attended the rheumatic unit at St. Stephen's Hospital. Timbrell Fisher's studies on the pathology of arthritic joints, combined with his clinical ability as a manipulator and orthopaedic surgeon, his personal humility, and his willingness to co-operate with the other members of the team, made him a valuable and delightful colleague as well as a first-class postgraduate teacher. Although he realized his own ability, and fought for what he wanted, he was a shy man.

He had few interests outside his work. He had a deep love of the countryside, and enjoyed long walks on Exmoor and in the Quantocks. His first wife, by whom he had two sons and a daughter, died in 1953. Later he remarried, and continued in consulting practice up to the time of the death of his second wife in July of this year. We will miss a good companion, a conscientious, friendly man, and one who had a full and useful life.

L. SURZYNSKI, M.D.

Dr. L. Surzynski, general practitioner in Maida Vale, London, and president of the Polish Medical Association in Great Britain since 1949, died on 28 September. He was 75.

Leon Surzynski was born in Inowroclaw, Poland, on 8 April 1891, which at the time was under the German partition. He received his primary and secondary education in Inowroclaw, and completed his medical studies at Leipzig and Munich Universities, graduating M.D. at Leipzig in 1917. During his undergraduate years he took an active part in the Polish independence movement. Between the years 1918 and 1922 he served initially in the German Army, and subsequently in the newly formed Polish Army under the leadership of Jozef Pilsudski. Jozef Pilsudski later became Marshal of Poland, and Dr. Surzynski was always a fervent supporter of his ideals. During the years of Poland's independence he took an increasing interest in politics, at the same time maintaining his private practice in Poznan. This political interest led him to become a member of the Polish Diet in 1928; and in the last sitting of the House between 1935 and 1939 he was elected deputy leader. In the Diet he represented the part of Poland known as Wielkopolska, and for a period of time was a city councillor of Poznan—his home town. In appreciation of his services to Poland he was awarded the Polonia Restituta, the highest Polish civil order, and the high military order of the Cross of the Valiant.

Apart from his chosen fields of medicine and politics, Dr. Surzynski was a very talented musician. He was president of many musical societies, but devoted most of his time to the Polish choirs. He was president of the Choral Society of Poland, and of the Slavonic Choral Society. During the last 20 years of his life spent in London he further pursued his interest in Polish choral music, and was the leader and organizer of the Polish choirs in Great Britain. During the second world war he was the chief medical officer for the Y.M.C.A. in Bucharest between 1939 and 1940. In 1941-2 he was the president of the Polish Red Cross in Jerusalem. From 1943 to 1946 he was liai-

son medical officer to the British Mission of Johannesburg.

After the war he came to London, where he spent the remainder of his life. He was always deeply concerned about the welfare of the Polish refugees in Britain. He maintained an interest in the Polish Army hospitals, and as president of the Polish Medical Association he was associated with the Polish medical school attached to Edinburgh University. He was separated from his wife and family, who had remained in Poland until 1958, when his wife joined him in London. In the last years of his life he was primarily concerned with the running of his practice in Maida Vale. His hospitality knew no bounds, and his guests could be certain of a warm welcome, with entertaining conversation and excellent music provided by the host. In him we have lost a great Pole, a fine doctor, and a man with a keen social conscience. Dr. Surzynski had an extremely amiable and dynamic personality, and will be remembered and loved by friends and patients alike.

We extend our deepest sympathy to his widow, two daughters—one of whom has followed him into the medical profession—and grandchildren in Poland.—J. T. L. and J. K.

K. J. L. SCOTT, M.D., M.R.C.P.

Dr. K. J. L. Scott, a general practitioner in Woking, died in the Nuffield Nursing Home on 26 September. He was 69.

Kenneth James Langlands Scott was born in Waimate, New Zealand, on 6 October 1897, and received his medical education at Otago University, graduating M.B., Ch.B. in 1922; two years later he proceeded M.D. That same year he was offered a post at the Mayo Clinic, but decided to come to Britain, where he took the M.R.C.P. shortly after his arrival. His early interest was in cardiology; he studied under Sir James Mackenzie, and was appointed Patterson research scholar in cardiology at the London Hospital. On the death of Sir James he settled in practice in Woking. During the second world war he served in the Indian Medical Service in the Middle East, attaining the rank of lieutenant-colonel. After demobilization he returned to his practice, but still maintained his particular interest in cardiology, giving his patients the benefit of his considerable experience. He was closely connected with the Woking Victoria General Hospital, and was for many years its medical director and senior physician.

Kenneth Scott pursued his hobbies with boundless enthusiasm and considerable success. As a philatelist his collection of early New Zealand stamps and postmarks earned him a reputation in this field. From his own vineyard he produced up to 200 bottles of wine a year, and was honoured by being made a Chevalier du Tastevin de Bourgogne. In his practice he never spared himself. Despite failing health latterly, he insisted on giving his patients the same care and attention he had always done. To his wife and four daughters go the sympathy and affection of his patients and friends.—F. M. L.

A memorial service will be held for Professor H. A. Magnus at King's College Hospital in the Hospital Chapel at Denmark Hill, London S.E.5, on 26 October at 3 p.m.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 30 September (No. 39) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included) Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Aldomet[®]
Methyldopa BP

**for smoother, long-term
control of hypertension**

She will appreciate the convenience of Candeptin Vaginal Tablets, a new extension of the specific treatment for monilial vaginitis

Rapid symptomatic relief¹ and decisive resolution of infection² are the proven results of Candeptin vaginal ointment in the treatment of monilial vaginitis caused by *Candida albicans*. Now Candeptin vaginal tablets provide the same effective fungicidal treatment (candicidin), in a more convenient form. They are "... easier to use, and appear more suited to obstetrical patients, in whom an applicator might be contra-indicated".³

IN THE LABORATORY

candicidin has been shown⁴ to inhibit *Candida albicans* at 0.05 mcg/ml even after two days' incubation. Under the same circumstances nystatin had to be used at 5 mcg/ml to achieve inhibition.

IN CLINICAL PRACTICE^{1,2,3,5,6}

Candeptin gives equally remarkable results. Out of 312 women treated, both pregnant and non-pregnant, 255 were cured after one course of treatment. A further 33 responded to a second course giving an overall success rate of 93%.

MEDICAL NEWS

Sir Arthur and Lady Porritt

The British Medical Association gave a dinner on 10 October in honour of Sir ARTHUR PORRITT, Governor General Designate of New Zealand, and Lady PORRITT, at B.M.A. House. Among those present were the following Past-Presidents: Lord COHEN OF BIRKENHEAD, Sir IAN FRASER, Sir JOHN MCNEE, Sir CLEMENT PRICE THOMAS, Sir TUDOR THOMAS, Sir ARTHUR THOMSON, Dr. E. A. GERRARD, and Dr. ALEXANDER H. HALL. The guests were accompanied by their ladies. Mr. R. V. COOKE, President, presented Sir Arthur with an inscribed silver cigarette box and Lady Porritt with a cut-glass and silver powder bowl. Sir ARTHUR presented the B.M.A. with a silver condiment set. He is expected to leave for New Zealand on 26 October.

William Budd Memorial Tablet

On 16 October Mr. R. V. COOKE, President of the British Medical Association, unveiled a plaque to the memory of William Budd at George's bookshop, Bristol, the house

(Photo Prints (Bristol))

in which he lived from 1853 to 1855. The unveiling was preceded by a meeting in the Alfred Marshall Building at which Mr. JOHN TOTTERDILL described life in Bristol in Budd's time and Professor R. C. WOFINDEN spoke about Budd and his career. Professor T. F. HEWER, professor of pathology at Bristol University, presided. The ceremony was held under the auspices of the West of England Branch of the Society of Medical Officers of Health in association with the Bristol Division of the British Medical Association, Bristol Medico-Chirurgical Society, Bristol Civic Society, and George's bookshop.

Sheffield University

Professor R. KILPATRICK has been appointed head of the department of pharmacology and therapeutics at Sheffield University.

The title of Sir Ernest Finch Visiting Professor has been conferred on Sir HEDLEY ATKINS, P.R.C.S., and on Sir EDWARD WAYNE for the period of their respective visits to Sheffield during 1967-8.

Chair of Anatomy, Tasmania

Dr. COLIN PETER WENDELL SMITH has been appointed to the chair of anatomy in the University of Tasmania. Dr. Wendell Smith, who is 40, was educated in Derbyshire and at Watford Grammar School, qualifying from St. Bartholomew's Medical College in 1951. He joined the staff of Guy's Hospital Medical School in 1956 as junior lecturer in anatomy, and had been lecturer in anatomy there for three years when in 1961 he was appointed associate professor of anatomy in the University of New South Wales. He is at present working at Guy's Hospital Medical School as a Commonwealth Medical Fellow under the Commonwealth Scholarship and Fellowship Plan. His principal research interest is in the relationship between the neuron and its satellite cells, and earlier studies in this field have been followed up by investigations into the structure and function of neuroglia.

(Photographia Ltd.)

Minister Opens Hospital Extensions

The Minister of Health, Mr. KENNETH ROBINSON, officially opened last week a new operating-theatre suite and extensions to the outpatient and other departments at St. Helier Hospital, Carshalton. Similar improvements to hospital efficiency, he said, could be seen all over the country. It was not only in the development of new district general hospitals or in the provision of additional beds that the hospital service was making progress but also in the modernization of specialist departments such as pharmacies, physiotherapy departments, and outpatient departments. The provision of a modern hospital service lay largely in the upgrading and re-equipping of specialist departments. By improving them the best use could be made of existing beds. The Minister was introduced by LORD ADDISON, chairman of the South-west Metropolitan Regional Hospital Board.

Gift to Glasgow University

Glasgow University has been given £30,000 by Mr. ALEXANDER STONE, chairman of the British Bank of Commerce, towards the building of an advanced microbiology research unit at Garscube, Glasgow. The unit will be in the charge of Professor Iwo R. W. LOMINSKI, head of the department of microbiology.

Butterworth Gold Medal

The winner of the Butterworth Gold Medal for this year's essay, the subject of which was "The Manifestations of Senility and their Management," is Dr. M. K. THOMPSON, of Croydon, Surrey.

Accidents at Work

Speaking in London last week at a conference on industrial safety, Mr. RAY GUNTER, Minister of Labour, pointed out that the time lost over a 12-month period through industrial injury and industrial

disease was more than 23m. days, compared with about 2m. days lost in disputes. Of 372 fatal accidents in factories last year 100 might have been prevented by reasonable foresight on the part of the employer or occupier. In 91 instances the deceased was considered to have been primarily responsible. Attention to safety, he said, should be brought home to employees by effective safety policies, especially in regard to sound training and competent supervision. A safe work-place and a safety conscious work-force were the ultimate objectives.

Broadmoor Hospital to be Rebuilt

The MINISTER OF HEALTH has decided in principle that the special hospital at Broadmoor should be rebuilt on its present site. It is intended to reduce the number of male patients, at present about 680, to a maximum of 500. The remainder will be transferred to a new hospital to be built, possibly on land adjacent to the special hospital at Moss Side, Maghull, Liverpool.

Harveian Oration

LORD PLATT delivered the Harveian Oration on 18 October at the Royal College of Physicians of London. His subject was "Medical Science: Master or Servant?" The Oration will shortly be published in the *British Medical Journal*.

Coming Events

Glasgow University Club, London.—Annual dinner, 2 November, 7 p.m. for 7.30 p.m., Cumberland Hotel, London W.1. LORD TODD, F.R.S., will preside. Details from Dr. J. F. HEGGIE, North Middlesex Hospital, London N.18.

King Edward's Hospital Fund for London.—Conference on ward housekeeping experiments at Whittington Hospital and Greenwich District Hospital, 1963-7, 9 November, Hospital Centre, 24 Nutford Place, London W.1. Details from Miss J. B. CRAIG.

Royal College of Obstetricians and Gynaecologists.—Scientific meeting, 17 November, Newcastle upon Tyne.

Leeds School of Medicine.—Annual dinner, 17 November, 7 p.m. for 7.30 p.m., Griffin Hotel, Boar Lane, Leeds 1. Tickets (35s.) from Honorary Secretary, Dinner Committee, Medical School, Leeds 1.

Institute of Religion and Medicine.—Open meeting, 17 November, 5.30 p.m., Friends' House, Euston Road, London N.W.1. Dr. MARGARET MEAD will speak on "Reward and Punishment."

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 23 October

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.

INSTITUTE OF DISEASES OF THE CHEST.—6.15 p.m., Dr. G. Simon: Radiology in the Patient with Dyspnoea.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., (1) Dr. A. Karen (Brno): Some Problems of Atrophic Rhinitis, Scleroma and Ozaena; (2) combined staff consultation clinical meeting.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr. B. W. Meade: Pathology of Trauma—Metabolic Consequences; 6.30 p.m., Dr. T. L. Dormandy: Aspects of Homeostasis—Osmolality. ●

MANCHESTER MEDICAL SOCIETY: SECTION OF GENERAL PRACTICE.—At Large Anatomy Theatre, Manchester University Medical School, 9 p.m., Dr. G. M. Komrower: Early Diagnosis of Mental Retardation with particular reference to Detection of Biochemical Upsets giving rise to Mental Handicap.

MANCHESTER MEDICAL SOCIETY: SECTION OF ODONTOLOGY.—At Lecture Room, Dental Hospital, 5.30 p.m., presidential address by Professor J. L. Hardwick: Trace Elements and Dental Caries.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Professor Sheila Sherlock: Hepatic Reactions to Drugs.

Tuesday, 24 October

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. J. M. Barnes: Toxic Substances and the Nervous System.

EDINBURGH UNIVERSITY MEDICAL STUDENTS COUNCIL.—At Lecture Hall "A," Hume Tower, George Square, Edinburgh, 5 p.m., B.M.A. lecture by Dr. Alex Comfort: "The Control of Ageing."

INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. D. D. Munro: Biology of Hair Growth.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammesmith Hospital, 2 p.m., Mr. C. K. Vartan: Breech Presentation. (Admission by ticket only, obtainable from Secretary, Institute of Obstetrics and Gynaecology, Chelsea Hospital for Women, London S.W.)

MANCHESTER MEDICAL SOCIETY.—At Large Anatomy Theatre, Manchester University Medical School, 4.30 p.m., university lecture on the history of medicine by Dr. W. Brockbank: The Early History of Our Medical School.

NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., Dr. R. Howell: cases and discussion.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Mr. D. J. Waterson: Surgical Paediatric Problems in the Services.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian lecture by Professor M. H. Irving: The Sympatho-adrenal Factor in Haemorrhagic Shock.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Mr. W. J. Dempster: Symptomatology of Rejecting Kidney Homotransplants.

SOCIETY OF CLINICAL PSYCHIATRISTS.—At Royal Society of Medicine, 6.30 p.m., discussion by Dr. H. V. Dicks, Professor W. Linford Rees, Dr. D. Williams: The Role of the Psychiatrist in Contemporary Society.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. G. A. D. Gordon: Ultrasonic Techniques in Neurology and Neurosurgery.

WESTMINSTER HOSPITAL MEDICAL SCHOOL.—8 p.m., Dr. R. M. A. McClelland: Information Retrieval.

WHIPPS CROSS HOSPITAL.—At Medical Education Centre, 1 p.m., clinical meeting.

Wednesday, 25 October

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.

INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. L. Szur: Principles of Dermatological Radiotherapy—II.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Peppy: Pulmonary Hypersensitivity Disease due to Inhaled Organic Dusts.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 3 p.m., Mr. A. M. Sutherland: Pelvic Tuberculosis. (Admission by ticket only, obtainable from Secretary, Institute of Obstetrics and Gynaecology, Chelsea Hospital for Women, London S.W.)

INSTITUTE OF UROLOGY.—5 p.m., Dr. C. S. Ogg: Blood and Urine Changes in Renal Disease.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—At X-ray Department, Kingston Hospital, 1.30 p.m., demonstration of radiographs by Dr. M. A. Hewett: Some Common Upper Abdominal Conditions.

OXFORD UNIVERSITY MEDICAL SCHOOL.—At Nuffield Maternity Home Lecture Theatre, Radcliffe Infirmary, 5 p.m., Dr. K. D. Bardhan: Intrinsic Factor.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Arnott demonstration by Mr. E. H. Cornelius: Some Presidents of the College and their Contribution to the Museum and Library.

ROYAL FREE HOSPITAL.—5.15 p.m., Dr. C. Leevy New Jersey: Liver Disease of the Alcoholic.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conference by Professor J. F. Goodwin, Dr. E. Olsen: Cardiomyopathy. (2) 2 p.m., Dr. J. S. Cameron: Proteinuria.

STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., films: Jugular Venous Pulse; Cardiac Output in Man. (2) 6 p.m., lecture by Mrs. C. Pepler.

WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Professor T. A. J. Pranker: Management of Anaemia.

WHIPPS CROSS HOSPITAL.—At Medical Education Centre, course for general practitioners, 2 p.m., Dr. J. E. M. Glancy: Sexual Deviation; 3 p.m., Dr. W. Walther: Use of the Autoanalyser for Multiple Analyses.

WHITTINGTON HOSPITAL.—At Academic Centre, Archway Wing, London N., 11.30 a.m., Dr. Deborah Doniach: Autoimmunity in Liver Disease.

Thursday, 26 October

ABERDEEN UNIVERSITY FACULTY OF MEDICINE.—At Large Lecture Theatre, University Medical Buildings, Foresterhill, 5 p.m., Dr. J. M. Walshe: Wilson's Disease—a Triumph of Hope over Experience.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. D. B. Hope: Storage of Polypeptide Hormones.

CHADWICK TRUST.—At 90 Buckingham Palace Road, London S.W., 5 p.m., paper by Surgeon Captain F. P. Ellis: Health of the Navy—the Changing Pattern.

DUNDEE UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Dr. J. A. R. Lenman: Applied Physiology in Neuromuscular Disease.

GALENICALS, UNIVERSITY OF BRISTOL MEDICAL STUDENTS' SOCIETY.—At Lecture Theatre (E.29), New Medical School, Bristol, 5.15 p.m., B.M.A. lecture by Professor R. S. Illingworth: "Bad Treatment."

INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. P. D. Samman: Principles of Dermatological Treatment.

LONDON HOSPITAL MEDICAL COLLEGE.—At the College Hall, Ashfield Street, 4.30 p.m., Schorstein memorial lecture by Sir Reginald Watson-Jones: Amputations of Body and Mind.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Thomas Vicary lecture by Sir Clifford Naunton Morgan: Surgery and Surgeons in 18th Century London.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 4 p.m., Mr. J. I. Burn: Management of Early Cancer of the Breast. (2) 5 p.m., lecture on medical history by Dr. E. S. Clarke: Disease in pre-Greek Antiquity.

RUNWELL HOSPITAL.—At Wickford, Essex, 8 p.m., Dr. T. M. Caine: A Five-year Follow-up of Treated Neurotics, Assessing Changes in Symptoms, Attitudes and Personality Tests.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Mr. R. G. Law: Standards of Obstetric Care.

Friday, 27 October

BROOK GENERAL HOSPITAL.—2 p.m., Mr. A. Howarth: Globus Hystericus.

NORTH STAFFS MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At Hartshill, Stoke-on-Trent, 8 p.m., Dr. D. W. Liddell: Temporal Lobe Epilepsy.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5.30 p.m., clinicopathological conference with cases from St. Mary's Hospital.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. J. Lorber: Current Problems in the Treatment of Hydrocephalus, and Long-term Results of Treatment.

Saturday, 28 October

CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—At Postgraduate Lecture Theatre, Addenbrooke's Hospital, 10.30 a.m., all-day symposium: Old Age and Anaesthesia.

NUTRITION SOCIETY: SCOTTISH GROUP.—At University Medical Buildings, Foresterhill, Aberdeen, 11.15 a.m., symposium: Diet and the Central Nervous System.

WHIPPS CROSS HOSPITAL.—At Medical Education Centre, 10.30 a.m., Dr. K. W. G. Heathfield: neurological ward round.

Sunday, 29 October

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—10.15 a.m., seminar for general practitioners by Mr. R. F. McNab Jones.

ROYAL NORTHERN HOSPITAL, LONDON.—10 a.m., clinical conference by Dr. W. E. Clarke.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council held on 12 October, with Sir Hedley Atkins, president, in the chair, Mr. R. V. Cooke was readmitted as a member of the Council of the College.

Dr. J. T. Priestley was admitted to the Honorary Fellowship of the College.

Lord Cohen of Birkenhead was appointed Thomas Vicary lecturer for 1968.

The death of Sir James Learmonth, Honorary Fellow, was reported with deep regret.

Colonel S. H. Janikoun was admitted as the professor of military surgery.

The Lady Cade medal was presented to Air Vice-Marshall G. H. Morley.

The Hallett prize was presented to Dr. Solomon Victor (Madras Medical College).

Mr. G. L. Scott, of Merchant Taylors' School, Crosby, Liverpool and Guy's Hospital Medical School was admitted as the Macloghlin scholar for 1967.

Mr. M. Bewick was appointed as the Johnson and Johnson research fellow on wound healing in the department of physiology of the College. Diplomas of Membership were granted to D. F. Abbott, J. R. O. Collin, S. I. Lewis, and J. L. Watts.

Diplomas of Fellowship were granted to M. Bewick and V. K. Kak.

Diplomas of Fellowship in the Faculty of Anaesthetists were granted to the following:

R. S. Peachey, D. I. Hughes-Davies, W. H. Morton, B. Hayes, Abigail E. E. Mensah, Margaret L. Shaw, J. F. Murray, Gillian M. Davies, T. I. Cash, G. W. Gamlen, I. P. Unsworth, R. A. Spilsbury, Valerie A. Codman, C. M. A. Bell, Elizabeth A. Binsted, D. G. Lewis, J. B. Williams, R. Loveday, D. G. Nancekivell, D. W. M. West, I. Ul Haq, P. L. Mulrooney, M. K. Sen, W. T. Fothergill, Norma E. Davies, R. W. Hall, T. R. Austin, S. J. Lines, Margaret E. Beveridge, T. A. Fraser, L. A. G. Jayasekera, A. A. Khawaja, H. Padmanabhan, J. K. G. Pigott, M. S. Y. Khalil, S. K. Mitra, S. K. H. Desai, J. Restall, S. H. Tan, Margaret D. Tyrrell, R. S. Ahearn, J. M. Anderton, W. W. Biggs, J. A. Bushman, B. R. S. McClements, W. Németh, C. M. Bowkett, S. de Lange, Isobel R. Mackay, J. B. H. Magner, Judith A. Radcliffe, D. M. Ross, R. I. R. Sinton, D. J. Turner, J. R. B. Young, R. A. Bond, Audrey Clarke, J. B. Dyson, A. I. Gurubatham, A. E. Heenan, B. M. Jones, P. R. Pridaux, Tri-Ratna M. Tuladhar, Ann V. Beaugie, Carole A. Brown, D. N. Davies, H. A. Edwards, W. Fitch, P. F. Reilly, Rehana Shafi, D. P. Winder, Ann B. Brown, J. H. Kerr, D. Leivers, S. W. Lim, J. McV. Loudon, J. Swinney, R. J. N. Turner, P. L. Jones.

Diplomas were granted, jointly with the Royal College of Physicians of London, to the following:

DIPLOMA IN OPHTHALMOLOGY.—E. El T. A. Abdalla, N. Ahmad, A. R. M. Al-Saleh, D. R. Amies, Than Aung, I. A. Ayesh, K. I. Badli, E. H. Barnout, M. H. Bhimani, M. Boossia, R. W. Bors, R. M. Brown, S. P. Brumley, L. Condons, M. S. Davies, S. C. Debnath, R. S. Dhillion, D. G. Emery, Helen M. Evans, V. H. Gandhi, M. G. Glasspool, N. Gregoratos, Abdul-Munim A. Hamid, G. C. Hipwell, M. A. Hosain, J. M. Hudson, M. Hussain, Khiaie Myo, T. H. Kirkham, A. Kyaw, Seck-Kee Leong, M. K. J. Lim, W. E. McCready, A. K. Mathur, A. R. Menezes, D. Millington, Rachel E. Need, V. R. Patel, R. P. Pokhrel, A. K. Prasad, K. Rajaratnam, V. V. Rao, A. E. A. Ridgway, J. H. Sandford-Smith, M. A. Sattar, F. Suleiman, A. H. Taj, F. Tappouni, Mary M. Walshe, Y. M. Wan, R. G. Wilson.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—S. M. S. Rahman.

DIPLOMA IN ANAESTHETICS.—L. R. Green.

DIPLOMA IN PHYSICAL MEDICINE.—J. B. Baggott, H. C. Burry, J. V. Forner Valero, Jessie K. M. Easton, M. A. Fouda, Doreen V. Jayamaha, F. L. Johnson, R. W. Tinsley.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—J. M. Goodburn.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—S. H. Abraham, H. A. Addy, R. Andersen, P. G. Atkinson, N. K. Biswas, S. M. Budhdeo, S. Chan, G. Cust, N. D. Dhabuwala, B. Dumavibha, P. R. A. Gaffney, A. K. Ghosh, J. J. Gilbert, A. Howis, P. U. Isichei, Md. R. Islam, M. Jamal, T. D. Jones, C. K. Kaufman, A. N. Khan, A. Y. Khogali, Z. A. Lins, Hee-Tak Mak, M. Misherghi, K. N. Murray, J. Mutemurana, S. G. Ng, R. W. Okach, C. T. Oon, S. Prasad, J. L. Pretorius, G. D. Qureshi, B. D. Reid, S. C. Roy, Lydia Schellekens, R. R. Shah, J. A. Sheikh, B. I. Syed, S. W. Tarlton, D. E. Taylor, S. Tin Tun, Taw D. C. Weeks, F. J. Wilson, J. C. Wilson, R. P. Yadava, W. Zylstra.

DIPLOMA IN PATHOLOGY.—Ruth M. Perinpanayagam.

After the meeting the Gordon-Watson lecture was delivered by Brigadier J. M. Matheson on "Infection in Missile Wounds."

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387-4499. TELEGRAMS: *Atiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. ADVERTISEMENTS AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia. MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

Pointers

Intrauterine Transfusion: Workers in Newcastle concluded from their studies that in spite of the hazard this procedure has an important role in the management of some cases of Rh-haemolytic disease (p. 189).

Transepidermal Water Loss: Is greatly increased in patients with erythroderma, psoriasis, and ichthyosis compared with normal subjects. This may explain the hypothermia and increased B.M.R. found in some of these patients (p. 195).

Emergency Intracardiac Pacemaking: Discussion of bedside method of placement using intracavitary electrocardiogram picked up by pacemaker electrode as a guide in patients with Adams-Stokes attacks (p. 199).

Oxygen Therapy: In paediatric use knowledge of exact concentration of oxygen is important. Studies show that incubators generally fulfil manufacturers' specifications, and that the Oxyginaire Humidaire Tent was the most efficient of the tents tested (p. 201).

Colitis in India: Ulcerative variety is not rare, but diagnosed less often than in the West because of the frequency of infectious conditions of the bowel, lack of facilities for precise diagnosis, and lack of long-term follow-up (p. 204).

Congenital Cyanotic Heart Disease: Retinal vascular changes initially present revert to normal after surgical correction of cardiac lesion, but E.E.G. defects do not change because they are not due to simple cerebrovascular disturbance (p. 207).

Electrophoretic Studies and Cancer: Study of survival of radioiodine-labelled serum γ G-globulin showed that the different fractions broke down at different rates, and were different in a patient with cancer from a normal subject (p. 210).

Case Reports: Enzyme variant in congenital methaemoglobinemia (p. 212); Anaphylactic reaction after soap enema (p. 215); Fatality after phenformin overdose (p. 216); New wave in E.C.G. complex (p. 217).

Conferences: Chemotherapy of tuberculosis in developing countries (p. 230). European Association for Study of the Liver (p. 232).

Dyspepsia: Symptoms, diagnosis, and management of gastro-oesophageal reflux due to hiatus hernia (p. 218).

Clinicopathological Conference: Crohn's disease in patient with treated adult coeliac disease (p. 222).

Nobel Prizes: Leader (p. 185). Photographs (p. 247).

Abortion Bill: Debate in House of Lords (p. 245).

Joint Annual Meeting in Australia: Provisional programme (*Supplement*, p. 25).

Public Health Committee: Report of meeting (*Supplement*, p. 27).

Retirement Pensions: *Supplement*, p. 26.

Prophylaxis in Rubella

Since the recognition of the teratogenic properties of rubella virus a quarter of a century ago many attempts have been made to prevent the disease during the early months of pregnancy. Until recently the only practical method of prevention has been by passive immunization. The results of 25 years' experience with either convalescent plasma or serum, pooled gammaglobulin, or convalescent rubella gammaglobulin have recently been reviewed by R. Lundström.¹ In experimentally induced infections gammaglobulin was surprisingly ineffective,² while in clinical trials the degree of protection afforded by this form of prophylaxis showed wide variation, though in a number of studies a substantial degree of protection was shown.³⁻⁶

Several factors probably contribute to the disappointing results reported with gammaglobulin in the prevention of rubella compared with its more obvious effect against measles. It is clear from the data reviewed by Lundström that the results were in many instances based on a small number of individuals, of different age and sex, living under widely differing environmental conditions and subjected to varying degrees of exposure to rubella. From 1954 to 1963 there was no practical method of assaying the content of rubella antibody in the prophylactics. Dosage could be an important factor in determining the outcome, as it is known that the antibody content can vary from batch to batch.^{7,8} The time of administration is probably even more important in view of the newly discovered details of the pathogenesis of rubella and in particular the prolonged period of infectivity and presence of viraemia, both of which occur for several days before the onset of the rash. More important, however, is the fact that the assessment of the efficacy of gammaglobulin in rubella on the basis of clinical attack-rates is not very meaningful when so many infections are atypical or subclinical. Subclinical infection may be associated with viraemia and foetal damage,⁹ and the trials so far reported have not established whether gammaglobulin, which has been shown to reduce the clinical attack-rate, protects the foetus, or what is the true rate of infection in immunized persons who do not develop symptoms. Some of the answers to these problems were contained in two papers in the *B.M.J.* of 9 September.^{10,11}

Since 1954 gammaglobulin has been available to general practitioners in this country. In an earlier report J. C. McDonald⁵ showed that the clinical attack-rate in family contacts given 750 mg. or 1,500 mg. of gammaglobulin was 1.27%. In a group of untreated women observed at about the same time the attack-rate was 3.7%.¹² This suggested that the gammaglobulin had a protective effect, but the attack-rates were low in both groups and the two were not strictly comparable. Now McDonald and C. S. Peckham¹⁰ report a further study on the use of gammaglobulin and its possible protective effect on the foetus. During the period 1954-62 gammaglobulin was issued to 36,577 rubella contacts. The dosage varied from 750 mg. to 1,500 mg., depending on the availability of supplies.

Data were finally obtained on 30,764 contacts, of whom 370 (1.2%) developed rubella within 28 days of inoculation and a further 0.3% at intervals thereafter. Later in the epidemic the attack-rate rose from 1.2% to 2.5% and then to 3.25%. The overall attack-rate in 15,173 women exposed to family contacts was 1.95%. As with the earlier survey this seems a low figure, but it is not possible to tell what it would have been without gammaglobulin. Attack-rates of 12% to 30% in unprotected women have been reported in surveys elsewhere. The observations on the incidence of defects, however, are more enlightening. Six hundred and ten women developed rubella and 424 (70%) came to term, including 319 cases of failure of prophylaxis and 105 cases in which the mothers had been treated with gammaglobulin after the appearance of the rash. Of the 424 liveborn children observed at the first postnatal inquiry at 3-9 months of age, 13% were found to have defects, of which 9.2% were of the rubella syndrome type. At the second postnatal inquiry at 2 years of age the rates increased to 18% for total defects and 13.6% for rubella defects, mainly heart disease and deafness in various combinations. No cataracts were observed, but only 14% of the 424 women were exposed in the first eight weeks of gestation.

The incidence of defects in the 30,297 women who were in contact with rubella, but who escaped infection was very different. Information was obtained from all but 13%. At the first postnatal inquiry 2.6% were found to have congenital defects, of which 0.4% were of the rubella type, with 3.6% and 0.6% at the second inquiry. The type of defects were very different from those observed in the offspring whose mothers had had rubella. They consisted in the main of malformations of the central nervous system and the musculo-skeletal and cardiovascular systems—malformations that are to be expected in the normal course of events. Comparatively few cases of deafness were encountered and a difference was also noted in the incidence of patent ductus arteriosus in the two groups. This latter manifestation is commonly associated with congenital rubella and is usually found together with other rubella-type defects. Eleven cases of patent ductus were observed out of 93 (11%) cases of congenital heart disease in the group who escaped infection, compared with 8 out of 13 cases (62%) in the group whose mothers had had rubella. Thus there was no excess of rubella-type defects in this group as a whole. This in itself is an important finding; but what could not be determined was the actual number of women in contact with rubella who did not develop clinical disease and who escaped infection altogether. This, after all, is the real test of the prophylactic value of gammaglobulin.

Antibody tests for rubella have recently been developed, and these have been used by members of the Public Health Laboratory Service to study the matter in more detail. In a report prepared by D. N. Hutchinson and his colleagues¹¹ it was found that only 4.9% of pregnant women in the Manchester area did not possess rubella neutralizing antibody. This is a low figure, but it is known that the incidence of rubella antibody varies considerably from one population group to another.^{13 14} In further studies in six different areas in the Midlands and north-west the proportion of non-immune subjects was found to vary from 6% to 21%. In 30 non-immune contacts given 750 mg. of gammaglobulin, 26.7% showed evidence of infection with production of anti-

body (seroconversion), and in 29 contacts given an additional 1,500 mg. between 8 and 12 days after contact 31% showed seroconversion. All but one of the patients showing evidence of infection received an initial dose of gammaglobulin within three days of contact. This study also showed once again the very much higher risk from contact in the home than elsewhere. A quite marked variation in antibody titre was detected among the 16 batches of gammaglobulin, but the numbers of susceptibles receiving material from any one batch was too small for differences in protection to be determined. These results indicate that the true attack or infection rate is around 30%.

Despite the obvious shortcomings of gammaglobulin revealed by these studies it still has a role as a prophylactic, limited though it may be. With the development of the haemagglutinin-inhibition test for rubella,¹⁵ which is quicker and more sensitive than the neutralization test, it should be possible to study the problem further by concentrating on the use of gammaglobulin of high titre given to non-immune contacts with the minimum delay after exposure. The main difficulty in studying rubella is inherent in the natural history of the disease. Infected individuals can be shedding virus for such a long and variable time before the onset of symptoms—and for a comparable time in subclinical infections—that it is difficult to determine when first contact has occurred. These and other results point to the need for the development of a rubella vaccine. Progress has already been made in this direction. P. D. Parkman and his colleagues¹⁶ have reported preliminary findings with an attenuated rubella vaccine prepared in monkey kidney-cell cultures which produced seroconversion without symptoms of infection in vaccinated children, though a number were found to be excreting virus from the oropharynx, albeit in low titre. Since this report further vaccines have been developed and are now on trial in several areas.¹⁷ Special problems of safety and antigenicity have to be considered in the development of a rubella vaccine, and it is likely to be several years before such a vaccine could be put into general use. Nevertheless, great progress has been made in a very short time.

Men of Vision

The Nobel prize for medicine for 1967 is shared by Professor R. A. Granit, of the Karolinska Institute, Stockholm, Professor H. K. Hartline, of the Rockefeller Institute, New York, and Professor G. Wald, of Harvard University, Massachusetts, the feature common to their work being the analysis of the mechanism of vision.

Granit's analysis of the relatively slow electrical changes that take place when the eye is exposed to light—the electroretinogram, or E.R.G.—was the work that first brought him fame in the field of visual physiology. As with the electrocardiogram, the E.R.G. could be resolved into a number of components, so that the electrical events recorded from the cornea were the algebraic sum of both positive and negative variations.

Subsequent work has largely confirmed his basic postulates, though more precise and localized recording has revealed many instructive complications. From the E.R.G. Granit progressed to the study of the action potentials in single fibres of the optic nerve, studies that culminated in his “dominator-modulator” theory of colour vision. Thus certain fibres appeared to be carrying messages indicating the general luminosity of the stimulus while others, the modulators, appeared to indicate its chromatic quality. The modulators tended to group into three regions of the spectrum, and thus gave an electrophysiological basis to the Young-Helmholtz trichromatic theory. Granit's great achievements in electrophysiology spring from his realization that the retina is, indeed, merely an outgrowth of the fore-brain, so that the properties of the synapses within the retina, and the organization of its neurones, are by no means peculiar to this sensory system. His analyses of retinal electrophysiology were thus generalized, and nowhere is this better seen than in his classical book *Receptors and Sensory Perception*, published in 1955. Furthermore, this realization led him to expand his field of investigation so that the electrophysiology of the proprioceptors of muscles has now become his field of main interest. Thanks largely to Granit's studies and those of younger men from all over the world who gained their early experience in his laboratory, the importance of the spindle in the control of muscular contraction is being realized, while the complex control exerted on muscular action through the spindle by cerebellar and other motor centres is being elucidated.

Hartline, like Granit, made the vertebrate E.R.G. one of his earliest studies in retinal physiology, but very soon moved to a more simply organized eye—namely, that of the horseshoe crab, *Limulus*. This, like the insect eye, consists of an aggregate of “micro-eyes” or ommatidia, each with its own refracting apparatus, photosensitive cells, and sensory nerve cell. Study of a single ommatidium, with the single group of fibres emerging from it and running to the central nervous system, provided an opportunity to study clearly the electrical events following illumination. A single fibre of the optic nerve of the vertebrate eye is the axon of a ganglion cell of the retina—that is, of a second-order sensory neurone—but the fibre leading from the ommatidium is the axon of a primary sensory neurone (the eccentric cell), and thus the message should be much simpler. The results of Hartline's studies on this system, carried out with ever-improving techniques, form the solid foundation for present-day theories of sensory processes. Thus the concept of the “generator potential,” the slow non-propagated negative variation developing in the receptor cell, has received ample justification from his

records obtained with micro-electrodes inserted into individual eccentric cells.

Perhaps one of the most interesting discoveries was the mutual inhibition between ommatidia. For a long time it was considered that the responses in fibres emerging from adjacent ommatidia were independent of each other, since there was no clear-cut synapse on the visual pathway where interaction could occur. In fact, however, interaction has been detected, and is thought to occur in the plexus of fibres just outside the ommatidia. It probably represents a crude form of synaptic action, but this awaits elucidation. The importance of this particular aspect is the opportunity it gives to study quantitative aspects of inhibition, since it is becoming clearer, as the study of sensory physiology is pressed further forwards to the sensory and integrating areas of the cerebral cortex, that inhibition is far more important than excitation. Thus uniform illumination of the retina, which excites presumably every rod and cone, produces little or no response in the vast majority of neurones in the visual cortex. Only when the retina is excited by certain patterns of light and dark will these cortical neurones respond; and the mechanism by which this discrimination is achieved is by way of inhibitory processes taking place at successive levels of the ascending pathway.

Wald has devoted his energies to the elucidation of the chemical events taking place in the receptor following exposure to light and the reversal of these effects during dark-adaptation. The amounts of material available for analysis that can be obtained from a single retina are very small, so that special methods must be used to identify them. Wald's initial achievement, which brought him world-wide recognition, was the demonstration that one of the later products of decomposition is retinene, which proved to be a simple derivative of vitamin A, thus providing, incidentally, a rationale of the long-recognized relation between night-blindness and vitamin-A deficiency. Thus rhodopsin, the photopigment of the rods of most vertebrates, could be described as a protein molecule, opsin, with a prosthetic group, retinene. Subsequent studies showed the successive steps in the breakdown of the rhodopsin molecule that culminated in the splitting off of retinene and its conversion to vitamin A in the retina during exposure to light. These changes were “dark reactions” in the sense that, once the first change had taken place in response to light, the succeeding ones occurred on their own; they were the result of thermal, rather than photochemical, reactions. The question that interested the physiologist was the nature of the initial photochemical event that triggered off these later reactions, since it seemed likely that the electrophysiological event would be most closely related to this. Wald showed that one of the earliest events was the “change in shape” of the retinene molecule while it was still attached to the protein, opsin. The retinene molecule, by virtue of having several conjugated double bonds, could adopt a variety of *cis-trans*-isomeric forms; and it was shown that only when the molecule had two of these forms could it remain in stable association with the opsin molecule. In the so-called 11-*cis*-form it united to give the photopigment rhodopsin, while in the 9-*cis*-form it gave another pigment, isorhodopsin. It would seem, then, that the primary effect of light is to make the linkage between retinene and opsin “uncomfortable,” in the sense that the retinene is now no longer able to fit snugly into the opsin carrier. Because of this, the opsin may undergo some strain, and this strain leads to electrical changes, from which changes follow in the neurone associated with the rod—that is, in the bipolar

cell. Thus Wald's analysis of the chemical events resulting from the impingement of a quantum of light in the rod has carried us very close indeed to the recognition of the real nature of the photochemical stimulus.

These studies have been confined to the photopigments concerned with night vision—namely, rhodopsin, found in the rods of the great majority of vertebrates, and porphyropsin, found in the rods of fresh-water fishes. The two pigments mediate night vision and are apparently not concerned in the more complex daylight, or cone, vision, by virtue of which not only is light appreciated as such but also its qualitative variations are appreciated as colours. In recent years the investigation of the nature of the photopigments in the receptors concerned with daylight and colour vision, the cones, has been pursued in many laboratories. Wald long ago extracted a pigment from the chicken retina, which contains mainly cones, which he called iodopsin. It was entirely different in its light-absorption characteristics from rhodopsin, but like rhodopsin it contained retinene, and it underwent a similar series of chemical changes on illumination. This was only one pigment, however, and the trichromatic theory of colour vision demanded three pigments, contained in separate cones, as the basis for colour discrimination. It would seem that the methods of extraction that were adequate for the study of night-vision pigments were inadequate for extraction and separation of these three hypothetical pigments. And we owe to W. A. H. Rushton, of Cambridge, and R. A. Weale, of London, the detection of several daylight pigments in the mammalian retina. Their studies indicated the presence of red- and green-sensitive pigments; the presence of a blue-sensitive pigment was not demonstrated, probably because of the technical difficulties. The Japanese workers Hanoaka and Fujimoto measured the absorption of light by single fish cones, and found characteristic differences corresponding to what might well have been red-, green-, and blue-sensitive cones; fish cones were chosen because they were big enough to permit this type of measurement. Essentially similar results have been reported in the primate from the laboratories of Marks and of Wald, blue-, green-, and red-sensitive pigments having been described by Wald, for example. Thus the trichromatic theory of Young and Helmholtz has been unequivocally substantiated by modern physiological research.

Fall-out from Space Travel

The Russians' safe landing of a space ship on Venus is surely one of the most astonishing technical feats so far achieved by man. The skill and resources that have been devoted to it are of necessity immense. While the ultimate goal of space travel still remains a fairly remote possibility, enthusiasts for it, when challenged to justify the vast sums of money they manage to extract from governments, are apt to shelter behind something called "fall-out." This is the expression used when an invention or discovery made for one purpose turns out unexpectedly useful for a different purpose. Something spills over the side of the bandwagon, and a watchful backroom boy rushes in to catch it as it falls.

Many items of space fall-out are listed by Albert H. Schwichtenberg in a recent article,¹ one of three forming an "Aerospace Medical Symposium" in the *Journal of the American Medical Association*. Unlike a room or a factory,

a spacecraft cabin is hermetically sealed; moreover, airborne particles cannot "fall" to the floor. So contamination is far less tolerated. Consequently, methods of reducing it have been developed which can be beneficially applied to industry.

Violent oscillations can arise during take-off of a spacecraft under power, so in the interests of astronauts the frequencies which set up resonance in various parts of the body have had to be investigated. The results are applicable also to motor vehicles and industrial machinery. "Instrument packages" for monitoring the various physiological systems of astronauts have been developed to a high pitch never before attained, and Schwichtenberg mentions a bolometer, fixed near the carotid artery in the neighbourhood of the ear drum, which records minute changes of temperature to an accuracy between 1/100 and 1/1,000 C°. Research already done on the effects of radiation and on shielding and protective drugs could, the author points out, be useful in connexion with nuclear weapons. But it is to be hoped that this particular item of fall-out will be denied the opportunity to justify itself.

Research into weightlessness, which cannot be experienced on earth for more than a fraction of a minute at a time, would hardly be expected to provide fall-out. Yet it belies its name, for fall-out there is. So anxious are the space medicine men to establish the effects of weightlessness over far longer periods than astronauts have yet had to endure that they have experimented with the next best thing—almost total immersion in water. A notable fall-out from this research is the "dry water immersion bed," used for the treatment of intractable trophic ulcers.

So far 19 astronauts have spent a total of some 2,000 weightless hours in 25 flights, writes Charles A. Berry.² The longest flights have lasted 4, 8, and 14 days, and in these the blood of the pilots in command has shown deficits in red cell mass of 5%, 20%, and 19% respectively.³ However, this phenomenon, due to a haemolytic process, was not attributed to weightlessness but to the cabin atmosphere being 100% oxygen. The reason for the pure oxygen is that air pressure inside the cabin is kept at only one-third of the atmospheric pressure on the earth's surface, and the reason for this, in turn, is that experience with pressurized aircraft convinced the engineers that a higher internal pressure would be difficult to maintain.

The forecast, made before space flight actually began, that an atmosphere of 100% oxygen at low pressure would be harmful was only one of several that proved too pessimistic, and Berry mentions many others. The suits of the "space-walkers," for instance, showed no sign of the impact of micro-meteorites while they floated outside the ship, and still less of any puncture of the suits, inside which a pressure of a quarter of an atmosphere was maintained. But the first space-walker encountered unexpected difficulty which had not been foreseen even by the pessimists: his attempts to complete his "tasks" led to excessive heat and sweat, and he had to hurry back inside. Berry attributes this trouble to the combined effect of "the basic laws of physics producing action and reaction and the need to stop an action, the difficulty in trying to maintain position to do a task, the problems of mobility in a 3.5 lb./sq. in. (242 millibars) suit, some amount of heat

load in the space suit and the carbon dioxide level in the helmet." Another false prophecy, derived from experiments in aeroplanes, was that a period of weightlessness would reduce tolerance to subsequent violent deceleration on re-entry into the atmosphere, but though it reached a maximum of 8.2 g it was well tolerated.

The remaining article, by George J. Kidera,⁴ shows that the most frequent medical causes of commercial pilots being grounded are cardiovascular (52%) and psychiatric (17%).

Plan for Hospitals

A working party set up jointly in 1965 by the King Edward's Hospital Fund and the Institute of Hospital Administrators was asked "to consider how, if at all, the present pattern of hospital administration might need alteration in the light of the changes that have taken place since 1948 and of further changes that may be brought about during the next fifteen years by the development of District Hospitals." Its twelve members included one medical man, Professor John Anderson, of King's College Medical School, and two hospital matrons, the others being lay hospital administrators. The working party set themselves the task of considering existing systems of management of hospitals at district level, suggesting changes that might be required in these systems, and considering a management pattern for the future, bearing in mind the advent of district hospitals.

In its report,¹ recently published, the working party identified three features of the existing arrangements which it regards as unsatisfactory and tending to hamper efficient and economic management. They are, firstly, over-use and misuse of the committee system; secondly, the absence of a clear definition of the roles and responsibilities of the various senior officials and of their relationship one to another; and, thirdly, the absence in the organization of any one official holding overall responsibility and authority. The working party's recommendations are designed to overcome these defects and also to provide for the closer association which it foresees will develop between the hospital and the other health and welfare services in the community. Its proposals rest on "two basic assumptions about the hospital service 15 years hence." The first is that the Ministry or some other central authority will continue to administer the service, the district hospital remaining the lowest tier of a three-tier structure, and the second that the best management structure for a district hospital will be "that which extracts from scarce resources of money, labour, and equipment the maximum possible benefit for the patient."

It is proposed that the hospital management committee should be replaced by a district hospital board. This would still be appointed by "the regional agent of the central health authority," but would have far fewer members, consisting of an appointed chairman and seven other members, three of whom would be on it *ex officio*. There would be two community advisory committees, one concerned with general medical matters and co-operation with other health and welfare services, the other with the interests of patients and co-operation with the local community. The chairman of each of these committees would be *ex officio* a member of the board.

The task of the board is seen as "to administer the moneys allotted to it and formulate the necessary policy to run the District Hospital." Executive function would be delegated to a general manager responsible for running the hospital, who would also be an *ex-officio* member of the hospital board. The general manager would be assisted by four directors of service in charge of medical and paramedical services, nursing services, finance and statistical services, and general services. These posts would be full-time appointments, though the director of medical and paramedical services might initially need to be part-time. A hospital medical services committee would be appointed by the senior clinical staff to advise the director of medical and paramedical services.

The late Professor J. M. Mackintosh, who contributed much to the study of medical administration, often claimed that there were only two countries in which the head of the medical services was not a doctor—the United Kingdom and Abyssinia. Whether this is so or not, it is certainly true that in Britain—more particularly the southern half of it—there is a body of opinion which holds that in hospitals at all events the doctor's place is in the ward and the operating-theatre, not the board-room. Most doctors are in no doubt that the primary function of a hospital is to deploy certain forms of investigation and treatment in the most effective way. The notion that they are really specialized institutions to be run by appropriately qualified managers with the help of doctors is not true. Undoubtedly lay officials have an essential role in the successful management of hospitals, but it should not be the dominant one.

The working party's report, though presented as a contribution to long-term planning, is essentially a presentation of the case for lay administration of hospitals. As such, it ought to serve a useful purpose in stimulating the medical profession to clarify its thinking on the shape of things to come.

Health Education of Asian Immigrants

Hazards to which newly arrived Asian immigrants are prone include pulmonary tuberculosis^{1, 2} and venereal disease,³ the effects of intestinal parasites—in particular anaemia from hookworm infestation⁴—and accidents due to unfamiliar surroundings.⁵ Thus health education⁶ could make a valuable contribution to the wellbeing of these people.

The newly arrived immigrant may be seen by his own countrymen, by a family doctor with whom he is urged to register shortly after arrival, by local-authority medical, social, or educational workers, and by staff of the Ministries of Labour or Social Security. If all bear in mind the risk he may be running, they can offer preventive measures or treatment by the appropriate services. A recent symposium held by the Health Education Section of the Royal Society of Health in Bradford showed that during three years of keeping specific records the infant mortality rate among children born locally to Asian immigrants had fallen to that of the English population of similar housing and employment background; and numbers of new notifications of pulmonary tuberculosis and venereal disease were declining rapidly. This had been achieved in part by special attention to the organiza-

tion of medical and social services and by education in their use.⁷

Evidence from Bradford itself, discussed at the symposium, suggests that after the first few months of life in Britain the health problems of immigrants become little different from those of our own population. Dr. F. N. Bamford showed that the main causes of death of infants born in this country of Asian parents, such as prematurity and bronchopneumonia, had the same incidence as in the general population. Serious forms of malnutrition were rare, but suboptimal nutrition might still be a problem, though improving with economic circumstances and possibly with the impact of education. For example, he noted that the number of days on which meat was eaten had risen substantially after stay in this country. Only 3% of a sample of 1,442 Asian schoolchildren had a haemoglobin level of less than 10 g. per 100 ml. Out of more than 2,000 bacterial cultures of the stools of immigrants no significant excess of intestinal infections had been found. There were no general problems of inadequate cleanliness or personal hygiene.

The lack of knowledge among the immigrant population of the interpretation of signs and symptoms of disease, particularly in paediatric practice, has led to some difficulties in general practice. It is only the family doctor who can effectively educate his own patients to assess those symptoms which require medical attention and to appreciate the degree of urgency with which it might be needed.

Thus the main problems of health education for immigrants, other than those who are newly arrived, are related not so much to its content as to the techniques required to put it across. The cultural, social, and religious patterns of immigrants need understanding, for they have to be taken into account when advising patients on questions of diet, family planning, and mental health.

To help overcome the language barrier local authorities can appoint Indian and Pakistani liaison officers. Spoken communication in simple matters may be possible, and a mixture of Urdu and English is often understood. Written communication may need translation into four or five languages. Printing of simple documents of instruction—for example, directions on the use of drugs or attendance at surgeries and clinics—is not difficult and requires only a translator and access to photo-lithographical processes, both of which are available in most large towns. But not all immigrants are literate. Suitably staffed infant welfare clinics of the traditional pattern perform vital educational work.

At present the pattern of immigration is changing. Male workers are no longer arriving in large numbers, but their families are making a great impact. Children of school age rapidly become proficient in English, particularly where special instructional centres are provided. These educational methods frequently allow an emphasis on social instruction and prove invaluable in everyday matters of hygiene, clothing, and nutrition. School medical officers can play a valuable

part in co-operation with the staffs of schools in promoting health education.

As the way of life of the Asian immigrant becomes more settled, his health problems and so the health education he needs approximate to those of our own population. It would therefore be a mistake, both educationally and in the wider context of integration, for the basic aims of the community programmes intended for him to differ from those for the native of this country. What is especially needed is patience to give help and advice against the background of different cultures and languages and experiment in developing techniques for this purpose.

Students Abroad

Not all travellers abroad are swirling down the brain drain. Many in fact are enriching their experience in a way that will be greatly to the benefit of their countrymen, and if they can begin to do so while they are still students so much the better. With this in mind the British Medical Students' Trust was founded in 1958 by undergraduates for undergraduate education. It is a legally constituted charity now independent of the British Medical Students' Association, which established it, but with links through its board of trustees with both the B.M.S.A. and the B.M.A. The president is Lord Cohen of Birkenhead and the chairman of the trustees Mr. A. M. A. Moore. Through the generosity of industry—mainly pharmaceutical firms—and charitable foundations, as well as of individuals, the trust is able to finance visits abroad for about 30 to 50 medical students a year, some to advanced centres of study, others to exceedingly out-of-the-way places. In learning to help tackle unusual problems in strange conditions, often in the developing countries, the fortunate students chosen to go on these trips get the opportunity of helping people who need help and of discovering early on how much more there is to medicine than the textbooks contain. The trust has now launched a national appeal for funds, and it may be commended as a thoroughly worth-while cause. The address is British Medical Students' Trust, B.M.A. House, Tavistock Square, London W.C.1.

Meeting in Australia

Next year's Annual Meeting of the B.M.A. will be held jointly with the Australian Medical Association in August. The provisional programme appears in the *Supplement* this week to tempt readers in Britain to start making arrangements as soon as possible for a trip round the world. The theme, "A Review of Australian Medicine as at 1968," is aptly chosen, for British doctors cannot fail to be drawn to a country where independence of mind is highly esteemed and medical research in a lively condition. As well as the opportunity to see medicine afresh through Australian eyes, visitors are offered some suggestions for stopping off at places of interest on the way. Further details will be published when they are available, but it is not too soon to begin making arrangements for what will undoubtedly be a delightful and memorable occasion.

Intrauterine Transfusion in Rh-isoimmunization

Brit. med. J., 1967, 4, 189-194

Fifteen per cent. of all cases of Rh-isoimmunization end in stillbirth. Until 1963 the only available means of preventing this outcome in cases with a high risk of stillbirth was to deliver the foetus prematurely before intrauterine death had occurred. The value of this was limited, because many intrauterine deaths due to haemolytic disease of the newborn occur early in pregnancy, and because in the event of a live birth prematurity is a serious danger.

The introduction of intrauterine transfusion (Liley, 1963) offered the possibility that intrauterine life could be prolonged to a stage where premature induction could be more successfully employed, but implicit for its success and justification is a reliable forecast of the possible stillbirth and of the probable time of intrauterine death.

The present communication describes our selection of patients for intrauterine transfusion and our experience of the procedure as employed in the Newcastle hospitals during 1965 and 1966.

Selection of Patients

The final decision to carry out intrauterine transfusion depends on the level of bile pigment in the liquor amnii. Amniocentesis, however, involves risks, and to discriminate those patients in whom this procedure is justified use is made in the first place of the previous obstetric history.

Selection of Patients for Liquor Examination

At the first visit a patient can be placed in one of four categories:

(1) Patients currently developing antibodies—that is, first affected cases. The risk of stillbirth is only 8%, but this group comprises 60% of all cases. In these, intrauterine death tends to occur late in pregnancy, only 30% occurring before 37 weeks' gestation.

(2) Patients who have already had an affected infant who required no treatment. These families represent 10% of the total and carry no greater risk of stillbirth than pregnancy generally.

(3) Patients who have already had an affected infant who required transfusion. These families constitute 20% of the total; the risk of stillbirth is increased to 20%, but 40% of the stillbirths occur before 37 weeks' gestation.

(4) Patients who have already had a liveborn hydropic infant or a stillbirth due to haemolytic disease. This is the history in 10% of cases; the risk of a subsequent stillbirth if the foetus is Rh-positive exceeds 50%, and early intrauterine death often occurs. Walker (1960) estimated that after one previous stillbirth 50% of subsequent stillbirths occur in utero before 35 weeks, but after more than one stillbirth 50% die before 32 weeks' gestation.

If allowance is made for the size of and risk of stillbirth in each group it is calculated that the three groups carrying a significant risk of stillbirth contribute equally to the total stillbirths.

In 1965 and 1966 amniocentesis was carried out initially at approximately 22 weeks where previous stillbirth or very severe disease had occurred, at 32 weeks when there had been previous moderate disease, but at 35 weeks in first affected cases and only if the antibody titre exceeded 1/16 by indirect Coombs test. Liquor examination was usually repeated at intervals of two to three weeks.

Selection of Patients for Intrauterine Transfusion

There are many methods for estimating bilirubin in liquor, but we (Knox *et al.*, 1965; Savage *et al.*, 1966) have found that for predicting stillbirth at 34-36 weeks' gestation the critical liquor ratio transmission 520 $m\mu$ is 1.06. As the bilirubin level in liquor tends to fall as pregnancy advances it was appreciated that a higher ratio would have to be adopted earlier in pregnancy, and a level of 1.1 was arbitrarily chosen.

To assess the reliability of this criterion and the value of intrauterine transfusion we decided to carry out a controlled trial in 1965. Patients were admitted to the trial if the liquor ratio exceeded 1.1 early in pregnancy, but final selection for or against intrauterine transfusion was random.

In 1966 we discontinued the trial and were able to improve selection for intrauterine transfusion to include only those cases where the liquor ratio early in pregnancy was 1.1 or higher on two consecutive occasions and was not falling.

Our experience also enabled a second group of patients to be included for intrauterine transfusion—namely, those with a single ratio exceeding 1.1 at about 32 weeks. Previous to intrauterine transfusion such patients would probably have been induced at 32 weeks' gestation, but combining such serious prematurity with severe haemolytic disease had resulted in almost a 40% neonatal mortality. In comparison, in patients induced at 35 weeks the neonatal mortality is under 20% and after spontaneous delivery at term just over 2%. It was also appreciated that the technique of intrauterine transfusion is much easier at 32 than at 22 weeks' gestation.

Material

In 1965 16 patients were admitted to the trial and in seven intrauterine transfusion was carried out within two weeks of the initial liquor examination. Provided the foetus survived, intrauterine transfusion was repeated at intervals of two to three

|| Present address: University College Hospital, London W.C.1.

weeks until delivery, which in all cases was induced prematurely. The nine patients not selected for intrauterine transfusion also had repeated liquor examinations until delivery, which was also induced prematurely.

In 1966 28 patients with a high and rising bilirubin level were selected for intrauterine transfusion, which was carried out within three weeks of the initial examination. Intrauterine transfusion was repeated at intervals of two to three weeks until delivery by premature induction. Another 17 patients also had amniocentesis, but, either because the bilirubin level did not meet the criteria or very early intrauterine death occurred, they were excluded from intrauterine transfusion. Liquor examination in these also was repeated at intervals of two to three weeks where appropriate until delivery.

Technique of Intrauterine Transfusion

Before the initial amniocentesis placental location is carried out by percutaneous femoral arteriography (or by radioisotope scanning) to reduce the risk of placental damage.

We feel it is important to extend to the mother in advance an adequate explanation of the programme to be followed and of the technique. One hour before the transfusion she is sedated with Omnopon 1/3 gr. (22 mg.) and scopolamine 1/120 gr. (0.5 mg.) and is then transferred to the x-ray department, where the operation is carried out under local anaesthesia. By using an image intensifier and television screen radiation is kept to a minimum and a Videotape recorder allows playback for reassessment without adding to screening time. The detailed steps are as follows:

(1) We find it a valuable aid, especially for the earlier transfusions—that is, at 24 and 26 weeks' gestation—to take a flat x-ray picture, by means of an under-couch tube, of the mother's abdomen with a marker on the umbilicus, when she is positioned for the transfusion. Within five minutes, after automatic processing, the dry film can be placed over the abdomen like a map, helping accurate palpation of a small foetus and enabling site and direction of puncture to be marked on the skin.

(2) With full aseptic technique, and after local anaesthesia, the Tuohy needle is introduced into the amniotic sac and a specimen of liquor is taken. The needle is then advanced until the foetal peritoneal cavity is entered.

(3) To ensure that the needle is not in solid tissue 1 ml. of saline is injected, then 2–5 ml. of Hypaque 45% (sodium diatrizoate) is injected. Sometimes the classical pattern of demilunes is seen, confirming the correct siting of the needle, but we have found the outline of the foetal diaphragm to be more helpful, though it often takes longer to develop.

(4) When we feel certain that the peritoneal cavity has been entered, a fine epidural catheter is introduced through the Tuohy needle and the latter is withdrawn. Before any transfusion aspiration is carried out to remove as much of the radiopaque material as possible, but also to remove any ascites or residual blood that may be present. Ascitic fluid, being clear and bright yellow, can usually be distinguished from liquor, which tends to be paler and cloudy. If necessary the nature of the fluid is confirmed by estimating the protein content by a sulphosalicylic acid method.

(5) A three-way tap is connected to the epidural catheter and donor blood, which is connected to the tap by a Baxter disposable giving set, can be drawn into a 10-ml. syringe and slowly injected into the foetus. Because concentrated red cells are used and the catheter is fine, we have found it necessary to compress the syringe by means of a modified screw clamp. The closed circuit minimizes risk of infection.

(6) Liley (1963) originally recommended injection of 100 ml. of blood, but we attributed three deaths, at 26 weeks' gestation, which occurred shortly after the procedure to the injection of too large a volume, and have now found the following routine more satisfactory: 24 weeks 30 ml., 26 weeks 45 ml., 28 weeks 60 ml., 30 weeks 80 ml., 32 weeks and later 100 ml. Approximately five minutes is taken to inject 10 ml. of blood.

(7) On completion of the transfusion 50,000 units of crystalline penicillin and 100 mg. of streptomycin mixture in 2 ml. is injected

down the catheter and into the needle track as the catheter is withdrawn. We do not undertake routine antibiotic administration to the mother subsequently, and we have not as yet left catheters in situ between transfusions. No case of infection occurred.

Technique has been kept as simple as possible, and we have not found it necessary to inject radiopaque substance into the liquor in order that it may be swallowed to outline the foetal alimentary tract; nor do we think it wise to inject dye into foetal soft tissues to act as a marker.

We have not adopted Liggins's (1966) method of using a second needle to impale and steady the foetus during puncture of the foetal abdomen.

Selection of Blood for Intrauterine Transfusion

Appreciating that erythrocytes might be damaged by injecting through a fine catheter and by contact with radiopaque dyes, two preliminary experiments were carried out:

(1) Both time-expired and fresh blood concentrated to have a haematocrit of 80% was injected through the catheter at rates varying from 30 seconds to 10 minutes per 10 ml. The injected blood was then mixed with an equal volume of saline, and after centrifugation haemolysis in the supernatant was measured. Significant haemolysis occurred at all rates exceeding three minutes per 10-ml. injection. The potassium levels predictably were higher in rapidly injected blood, being on average 9 mEq when injected at the rate of three to seven minutes per 10 ml., compared with 18.4 mEq at 30 to 45 seconds per 10 ml.

(2) The blood having been injected through the catheter was mixed with radiopaque dyes in varying dilutions, and incubated at 37° C. for 2, 12, 24, and 72 hours. The amount of haemolysis in the mixture was estimated and the sample examined for spontaneous agglutination and assessed for reliability of ABO grouping. One part dye to 60 of blood was anticipated in the peritoneal cavity at intrauterine transfusion and at this dilution Myodil (iopendylate injection) caused 90% haemolysis in 72 hours and the remaining cells showed abnormal ABO grouping. Neo-Hydriol (iodized oil injection) gave similar results but is not recommended by the makers for intrauterine transfusion. Conray 480 (sodium iothalamate) caused spontaneous agglutination, false ABO grouping, and some haemolysis after as little as two hours' incubation. With Hypaque 45%, however, there was only a small amount of haemolysis even at 72 hours with a 1/60 or 1/30 dilution, but in higher concentration, particularly with Hypaque 66%, agglutination and some haemolysis did occur.

We have therefore used Hypaque 45% in minimal quantity, and before injecting blood have aspirated as much of the dye as possible. Like Liley (1965) we have found little evidence that Hypaque causes serious peritoneal reaction, though in two cases where it was accidentally injected into the thigh pronounced tissue necrosis occurred possibly causing temporary partial femoral artery occlusion in one infant. Deliberate injection of dye into soft tissue should be avoided.

Because delivery was not anticipated for several weeks after transfusion red cells not older than 48 hours have been used. To avoid the theoretical risk of injecting large numbers of viable lymphocytes red cells have been recovered from the bottom of bottles, avoiding the buffy layer, and we have preferred blood collected into acid citrate dextrose rather than into heparin. Concentrated red cells (haematocrit about 80%) minimize risks to the anaemic infant, including the injection of excess potassium or citrate.

Group O cde/cde blood was used for all cases, and care was taken to exclude donors with anti-A or anti-B haemolysins. Full compatibility tests with the mother's serum were performed, and in a number of patients selection has been difficult because of the presence of multiple antibodies.

By taking into account the ABO, Rh, and MNSs groups of the mother and father, it has usually been possible to select blood distinguishable from that of the parents, and sometimes from another donor used for a subsequent transfusion. We have thus, and by the Kleihauer *et al.* (1957) technique, been

able to identify and quantitate donor blood in the foetus at delivery and also in blood that may have escaped into the liquor or been retained in the peritoneal cavity or other sites in the foetus.

Accidents

Accidents with the procedure, despite careful technique, do occur, though these decrease as the operator becomes more experienced. Sites other than the peritoneal cavity may be entered, and in this series of 77 intrauterine transfusions the pleural cavity has been entered on two occasions, the pericardium once, the gastrointestinal tract twice, and the bladder three times. In no instance did this appear to cause any immediate trouble, and six of these eight infants were subsequently born alive with no apparent sequelae.

On one occasion we think the liver was punctured, and on resiting the needle in the peritoneal cavity 25 ml. of foetal blood was aspirated previous to the intrauterine transfusion. The infant was born 10 days later and survived. There was a puncture wound over the liver with extensive skin bruising. Extensive haemorrhage from the liver has been described (Gordon *et al.*, 1966), and may prove fatal.

On one occasion the spleen was probably entered, and though the foetus was stillborn it did not appear that the accident was responsible for the intrauterine death.

On seven occasions a small amount of foetal blood was obtained at the time of intrauterine transfusion, but only on the one occasion referred to did it exceed 1 ml.

The possibility that injection of blood into the peritoneal cavity might lead to adhesions and subsequent intestinal obstruction would seem plausible, and in two infants born alive after intrauterine transfusion there was evidence of partial intestinal obstruction in the neonatal period, but this responded to conservative treatment and did not result in permanent sequelae. In one stillborn foetus small adhesions between loops of bowel were shown at necropsy.

In three instances large collections—up to 50 ml.—of donor blood have been found in the musculature of the abdominal wall, which may have resulted from leakage from the peritoneal cavity, foetal bleeding, or because of the oedematous state of the foetus the injection being actually made into the abdominal wall.

Results in 1965

Though eight cases were selected for intrauterine transfusion, in one case the procedure was withheld because of a steadily falling liquor ratio after the 24th week, and an Rh-negative infant was born. Ten intrauterine transfusions were performed on the remaining seven patients, four receiving a single transfusion and three receiving two transfusions.

Table I shows 28% survival in the transfused group compared with 66% in those not transfused. The erroneous impression that intrauterine transfusion is of no value was brought about in two ways. The cases selected for intrauterine

transfusion were, by chance, much more severely affected than those not selected, based on the retrospective observations that the first liquor ratios were higher in the treated group (average ratio 1.37) than in the untreated cases (average ratio 1.18). Also, in the untreated group were the two patients with Rh-negative infants and two infants with only moderate disease. Secondly, early difficulties encountered with the technique probably contributed to some of the deaths in the treated cases. However, valuable information accrued from the trial. Thus experience with the technique seemed to lead to better results, and an important point learnt was that the injection of 100 ml. of packed cells into a small foetus may precipitate death. Further, liquor findings showed that in all cases where a normal or only a moderately affected infant resulted there had been a fall in liquor ratio between the first and second test; whereas almost without exception pregnancies resulting in stillbirth or very severe disease showed an increase in ratio between the two tests.

That a normal infant may be associated with a high liquor ratio in early pregnancy is illustrated in Fig. 1, which shows cases resulting in Rh-negative infants and where at least three observations were carried out. In normal pregnancy the liquor ratio before 24 weeks may exceed 1.1; up to 30 weeks it may exceed 1.06, but after 33/34 weeks the ratio is usually below 1.04.

FIG. 1.—Repeated liquor examinations in Rh-negative pregnancies.

Results in 1966

The 28 patients selected under the revised criteria received 67 intrauterine transfusions (Table II). The overall survival rate was 54%. In 9 of the 11 stillborn cases death occurred very shortly after the first intrauterine transfusion, and in each case ascites had been detected at the transfusion. However, ascites was also present on at least one occasion in 12 of the 16 liveborn infants. Two of these infants had ascites tapped on two occasions, one on three, and one infant on no fewer than four occasions, a total of 160 ml. being removed. This infant was not hydropic at birth and survived.

Total	28 (67 transfusions)	
Survival	54%	

Numbers in parentheses are of cases where first transfusion was after 31 weeks.

Only six of the patients were selected for intrauterine transfusion after 30 weeks' gestation, and of particular interest is one infant who at operation had 110 ml. of ascites withdrawn before transfusion was carried out. Ten days later the infant was born alive; no donor cells were detected in the circulation; the cord haemoglobin was 38%, and though the infant had generalized oedema no significant ascites was present.

The one Rh-negative foetus transfused was wrongly selected, but it is probable that the calculated E.D.D. was incorrect and that liquor examination had been at 28 rather than at 32 weeks' gestation; allowance for this would have excluded selection. At birth the cord haemoglobin was 140% and 50% of the cord cells were donor cells. The infant (weight 4 lb. 6 oz.; 1,980 g.) developed hyperbilirubinaemia of prematurity requiring exchange transfusion, also respiratory distress, but survived.

Sixteen of the 17 patients producing liveborn infants in 1966 had labour induced between 35 and 37 weeks' gestation. One patient came into spontaneous premature labour at 35 weeks—16 days after the last (fourth) intrauterine transfusion. In the

haemoglobin value in unselected cases of haemolytic disease is 100%. We failed to rationalize the amount of donor blood present at birth, even taking into account the size of the foetus and the number of donor cells injected, and allowing for estimated red cell survival. While this probably represented a failure of absorption in certain cases, several times donor blood has been recovered from the liquor. We think that occasionally a leakage back from the foetal peritoneal cavity occurs.

Eight infants were severely affected and treated within half an hour of birth, one having a cord haemoglobin of 18%, all of which was donor blood. Nine infants were moderately affected and were treated within nine hours and two, though

FIG. 2.—Direct Coombs test on (1) weakly Coombs positive infant; (2) strongly Coombs positive infant; and (3) infants after intrauterine transfusions with 20% foetal cells.

present series only one patient (3.6%) went into premature labour as a result of the procedure. In this case there was technical difficulty with the third intrauterine transfusion; the foetal bowel was entered, and when the catheter was finally properly sited, the needle having been removed, it was found to be blocked. The procedure was then abandoned. The next day the foetal heart was absent, and two days later labour began and a stillborn macerated infant was delivered.

During 1966 a further 19 patients were considered but not selected for intrauterine transfusion. In six the foetus had already died by 24 weeks' gestation. Of the remaining 13, excluded on liquor examination, five infants were Rh-negative and five were born alive between 36 and 42 weeks. Three were stillborn, two from causes other than haemolytic disease (one with placental insufficiency and cord prolapse, the other was an intrauterine death showing no obvious cause). The third stillbirth occurred where the mother's serum contained multiple antibodies (anti-D, anti-A₁, anti-Fy^a, anti-E, and a weak unspecified antibody). Though compatible blood for mother or infant was eventually found, it was thought expedient to reserve this for this time of delivery.

Severity of Disease in the Liveborn Infant

Nineteen affected infants were born alive after intrauterine transfusions. Some of the infants, owing to the presence of almost 100% Rh-negative donor cells, failed to show a positive direct Coombs test, while others gave a weak result. However, in these latter, where a few Rh-positive foetal cells—for example, 5% of the sample—are coated with a strong antibody, the pattern of Coombs test is quite different from the weak positive test due to many Rh-positive foetal cells being coated with a weak Rh antibody (see Fig. 2).

Cord haemoglobin values varied from 18 to 140%, and the proportions of adult and foetal blood are shown in Fig. 3.

It will be seen that the donor blood contribution to the cord haemoglobin at birth varied from 0 to 100%. The average cord haemoglobin was 66%, with 40% donor blood and 26% foetal blood. This represents severe disease, for the mean cord

not meeting our criteria for exchange transfusion, required simple transfusion later.

Cord bilirubin levels also indicate increased severity in these infants after intrauterine transfusion, with a range of 1.9 to 7.1 mg., and a mean of 4.2 mg., compared with a mean of 3 mg. in unselected material.

All of these infants were delivered prematurely, usually at about 35 weeks' gestation, and this policy is reflected in the

FIG. 3.—Cord haemoglobin values and percentage of donor cells in intrauterine transfusion cases.

birth weights, which ranged from 3 lb. 12 oz. (1,700 g.) to 7 lb. 5 oz. (3,315 g.), with a mean of 5 lb. 4 oz. (2,380 g.). Four infants were delivered by caesarean section because of failed induction, and a further three were delivered by caesarean section for other reasons (placenta praevia, foetal distress, unfavourable cervix). Six infants required resuscitation, though in only two was there prolonged difficulty in establishing respiration. Five infants developed respiratory distress, which was severe in two.

Six infants required two exchange transfusions, while one required four. We did not find, as has been reported in the literature (Bowman, 1966; Work *et al.*, 1966), that exchange transfusion was required frequently in cases treated by intra-

uterine transfusion. In such reports, however, many patients came into premature labour shortly after intrauterine transfusion, and possibly continued absorption, after birth, of donor cells from the peritoneal cavity aggravated the hyperbilirubinaemia (Fong, 1966):

Simple transfusion was required in 10 cases, a much higher incidence than in haemolytic disease of similar severity not treated by intrauterine transfusion. The prolonged anaemia may be due to depression of the bone marrow consequent on intrauterine transfusion. One infant with a cord haemoglobin of 28%, nearly all of which was donor blood, had a reticulocyte count of only 1%; and another with a cord haemoglobin of 18%, all donor blood, had a reticulocyte count of only 2%. One infant, who after five intrauterine transfusions required two simple transfusions, did not show an appreciable reticulocytosis until 14 weeks of life, and the Rh-negative infant, incorrectly selected, had a cord haemoglobin value of 140%, but the haemoglobin value in infant's cells was only 70%.

Three infants died. The cord haemoglobin values were 18%, 21%, and 26%. Cardiac arrest at the start of a second exchange transfusion was responsible in one case, pulmonary haemorrhage at 18 hours in another, and pulmonary haemorrhage and kernicterus on the fourth day in the third infant.

All surviving infants have been followed up at three-monthly intervals. At the time of writing the eldest was 18 months and the youngest 5 months. Developmental milestones, weight gain, and physical examination were normal in all but two. These exceptions are:

(1) An infant with severe haemolytic disease, heart failure, thrombocytopenia, and mild respiratory distress who was noticed to have a patent ductus arteriosus. At 6 months the ductus was still patent, and, though developmentally and physically normal, he was underweight.

(2) An infant with a cord haemoglobin of 38% with no donor cells demonstrable at birth suffered very severe respiratory distress, requiring 90% oxygen for 12 days with dextrose and intravenous nikethamide. At 1 year he was somewhat retarded and there was radiological evidence suggesting cerebral atrophy.

Congenital abnormalities were not a feature as in some reported series (Charles *et al.*, 1966). The only congenital defects observed, apart from the patent ductus, were two cases of squint. There have been no cases of deafness, even on audiometric examination, and there was no increase in the incidence of infection (Gordon *et al.*, 1966). Apart from the partial intestinal obstruction and partial femoral artery occlusion mentioned earlier, no complications in this series were attributable to the technique of intrauterine transfusion.

Discussion

Previous to any consideration of intrauterine transfusion it is well to remember that with conservative treatment 80% of all cases of Rh-isoinmunization will result in a living infant. In first affected pregnancies 90% will result in surviving infants.

Stillbirth occurs in 15% of cases overall and 50% of the stillbirths occur before 35 weeks' gestation. Those occurring late in pregnancy, if able to be identified, could be prevented by premature induction, but for those occurring early in pregnancy only intrauterine transfusion offers some prospect of help. The difficulties and dangers of the procedure, however, call for the most accurate possible selection of patients. In all published series the final selection has been based on liquor examination, but this necessitates amniocentesis, which is potentially dangerous. The majority of patients in whom early intrauterine death occurs are in the 10% of those who have a history of previous stillbirth or very severe disease. For these patients we recommend amniocentesis as early as 20 weeks' gestation. This is repeated, with or without intrauterine transfusion, at intervals of two to three weeks throughout pregnancy.

It should be remembered that the neonatal mortality in infants with severe haemolytic disease induced at 32 weeks is as high as 40%, compared with 20% in those induced at 35 weeks and 2% at term. Practically, intrauterine transfusion has done away with the need to carry out premature induction at 32 weeks, but though theoretically it should obviate entirely the need for premature induction in Rh-isoinmunization most workers still prefer, in the present state of knowledge, to induce labour when they think that the risks of prematurity are no longer overwhelming.

A second group of patients suitable for intrauterine transfusion can also be identified. We advocate amniocentesis at 32 weeks when a previous infant has been severely enough affected as to require any form of treatment. In this second group only one intrauterine transfusion should be needed. Subsequent refinements may select a small proportion of this group where amniocentesis earlier in pregnancy could be justified.

Because liquor bilirubin levels fall as pregnancy advances and because levels can be quite high at early stages of gestation even in normal pregnancy, very careful interpretation of the liquor results is necessary and there is need for accurate assessment of the stage of gestation (Walker, 1967). Our present criteria of bilirubin levels in liquor appear to be relatively satisfactory. We now carry out "early" intrauterine transfusion only if two consecutive values are higher than 1.1 and preferably showing a rise. However, in cases where the initial amniocentesis is made at 32 weeks intrauterine transfusion is performed if the ratio at that time exceeds 1.1.

The difficulties of the technique of intrauterine transfusion and the accidents that can occur have been covered in this report, but some points require special emphasis. We believe that the amount of blood injected, particularly into a small foetus, is important. Theoretically, exchange transfusion in utero (Adamsons, 1966) should be safer, but the greater dangers involved must restrict its use, and its contribution to the problem of intrauterine death can only be minimal. Liley (1964) originally regarded the presence of ascites as a contraindication to intrauterine transfusion, but 12 of our survivors had ascites removed on at least one occasion and Bowman (1966) has also reported survival in similar circumstances. It is desirable to avoid injecting large numbers of lymphocytes at intrauterine transfusion, for it appears that immunologically competent lymphocytes may occasionally colonize the reticuloendothelial system and produce complications (Cohen *et al.*, 1965; Kadowaki *et al.*, 1965; Githens, 1966; Naiman *et al.*, 1966).

Of course the later in pregnancy that patients are selected for intrauterine transfusion the better the results will appear; for not only is the operation technically more simple at later gestations but many of the very severe cases where intrauterine transfusion is especially applicable will already have resulted in stillbirth. In our 1966 series 21 cases initially treated before 30 weeks' gestation resulted in 11 stillbirths and 10 live births, whereas all seven treated after 30 weeks' resulted in live births. This point should be considered when evaluating published series.

In Table III we have summarized the three large English series. Though overall the survival rates were similar, the first point of difference is the time at which the initial intrauterine transfusion was carried out. Thus 75% of Newcastle cases were treated before 30 weeks' gestation, compared with 60%

TABLE III.—Time of Intrauterine Transfusion and Survival in Three Reported English Series

Gestation at First I.U.T.	Karnicki and Holman (1966) Lewisham		Gordon <i>et al.</i> (1966) Hammersmith		Present Series. Newcastle, 1966	
	Total	Survived	Total	Survived	Total	Survived
Before 30 weeks ..	19	3 (15.8%)	12	4 (33.3%)	21	9 (42.9%)
After 30 " ..	35	24 (68.6%)	8	6 (75%)	7	6 (85.7%)
All cases ..	54	27 (50%)	20	10 (50%)	28	15 (53.6%)

of Hammersmith cases and only 35% in the Lewisham series. The survival rate with these early transfusions was 43% in the Newcastle cases, 33% in the Hammersmith cases, and 16% in the Lewisham cases, but in each of the series the mortality rate was much higher in those cases treated before 30 weeks' gestation than in those treated later (with 70–85% survival).

Another point of difference was the onset of premature labour after intrauterine transfusion. This occurred within nine days of operation in 4% of the Newcastle cases, in 24% of the Lewisham cases, but in 65% of the Hammersmith cases. The reason for the difference is unknown but may be related to trauma or to leaving the catheter in situ between transfusions. Obviously if labour occurs early in pregnancy survival is jeopardized, and if later it is doubtful whether the foetus can have benefited significantly from the intrauterine transfusion. Indeed if large quantities of donor blood are still present in the peritoneal cavity after birth, continued absorption may contribute to the development of hyperbilirubinaemia (Fong, 1966).

Allowing for the severity of haemolytic disease and the degree of prematurity in the infants after intrauterine transfusion, we have not found particular problems in management except in one respect. The reticulocyte count on cord blood is often much lower than one would expect in relation to the haemoglobin level, and this erythroid hypoplasia persists longer and simple transfusion is required more often. Long-term follow-up, however, does not suggest any permanent defect. The leucocyte and platelet counts were not abnormal though increases in certain immunoglobulins have been noted (to be published). In the follow up of these cases, however, there has proved to be no difference in infection rates.

Though some of the deaths occurring immediately after intrauterine transfusion may have been due to technical difficulties, and certainly such cases have been recorded (Gordon *et al.*, 1966), no permanent sequelae have resulted in our surviving infants.

As regards neonatal death after intrauterine transfusion, we find that 3 out of 20 (15%) in Newcastle died, compared with 6 out of 16 (37%) at Hammersmith and 9 out of 36 (25%) at Lewisham. Perhaps comparisons of later series will produce more equitable results, but meanwhile the combined English series compares favourably with results from series in the rest of the world—up to February 1967 291 patients receiving 507 intrauterine transfusions with 118 (41%) infants surviving.

Provided that it is recognized that this procedure is not the panacea to prevent all Rh-stillbirths and that there is still difficulty in selecting the most suitable cases, there seems little doubt that, in spite of its hazards, intrauterine transfusion has a select and important part to play in the management of some cases of Rh-haemolytic disease of the newborn

“diseases desperate grown
By desperate appliance are reliev'd,
Or not at all.”—*Hamlet*, IV, iii, 9.

Summary

The criteria for selection of patients for intrauterine transfusion are discussed and experience with the procedure in 1965 and 1966 in the Newcastle upon Tyne hospitals is presented. Thirty-five foetuses received a total of 77 intrauterine transfusions, and 19 were born alive; 16 survived. It is concluded that in spite of the hazards intrauterine transfusion has a select and important part to play in the management of some cases of Rh-haemolytic disease.

We would like to thank our obstetric colleagues in the area who kindly referred patients to us. We would also like to record our appreciation of the considerable part played in this work by medical and nursing staffs of the Princess Mary Maternity Hospital and the Newcastle General Hospital, the staffs of the radiological departments at Newcastle General Hospital and the Royal Victoria Infirmary, and the staffs of the Regional Blood Transfusion Service and the Attic Laboratory. Without the co-operation of this team of people the studies described could not have been undertaken.

Skin Water Loss and Accidental Hypothermia in Psoriasis, Ichthyosis, and Erythroderma

KATHERINE A. GRICE,* M.B., B.S., D.C.H.; F. R. BETTLEY,* M.D., F.R.C.P.

Brit. med. J., 1967, 4, 195-198

Accidental hypothermia has been reported in patients with generalized eczema and other erythrodermas, the aetiology of the hypothermia being said to be obscure (Krook, 1960; Magnusson, 1960); rectal temperatures as low as 83-86° F. (28.3-30° C.) have been described. It has been suggested that hypothermia is related to the increased peripheral blood flow (Mali, 1952; Fox *et al.*, 1965). It has also been suggested that the heat loss in erythroderma is due to vaporization of water lost from affected skin, in these conditions the skin water loss being enormously increased (Zoon and Mali, 1957).

Hancock *et al.* (1929) pointed out that there are two kinds of water loss from the skin. The first is from sweating, the second from evaporation of water which has passed by diffusion through the epidermis, the corneous layer and its base behaving as a semipermeable membrane. The water loss by diffusion was designated by Rothman (1954) the transepidermal water loss.

The term "insensible perspiration" has been applied to the skin water loss, which is invisible to the naked eye, the sweat droplets evaporating as soon as they reach the skin surface (Jurgensen, 1924).

Few previous studies of the skin water loss have been done after inhibiting sweating, a satisfactory method for producing complete inhibition of sweating not hitherto being available.

In observations now reported the transepidermal water loss was measured in normal subjects and in patients with erythroderma, psoriasis, and ichthyosis.

Methods and Materials

The transepidermal water loss from normal skin was measured in 40 subjects after sweating had been inhibited with poldine. The apparatus and method have been described in detail previously (Bettley and Grice, 1965).

The apparatus, which estimates the total cutaneous loss from selected areas of the skin, consists of a collecting chamber placed on the abdomen, and dry air is passed over the skin. The amount of water is determined gravimetrically. Sweating is inhibited by the local application of poldine methosulphate (Nacton) (Grice and Bettley, 1966). The area of skin to be tested is marked out, painted with two or three coats of 2% poldine in alcohol, and covered with polyethylene, the edges being sealed. Next day the polyethylene is removed and the abdomen washed with soap and water; 4 to 24 hours later the transepidermal loss is measured.

The apparatus incorporates a thermistor for measuring skin temperature, and the presence of sweating is ascertained by the galvanic conductivity of the skin. The relative humidity in the collecting chamber was calculated from the measured skin water loss (mg./60 sq. cm./30 min.) contained in the total volume of air passing through the collecting chamber in 30 minutes (ml./30 min.) and the weight of water contained in saturated air at the air temperature in the collecting chamber. This was about 1-2° C. lower than the skin temperature.

* Institute of Clinical Research, Middlesex Hospital, London W.1.

The experiments were performed while the patients were at rest or sleeping, and the room temperature and humidity regulated so that sweating was minimal. The test lasted 30 minutes. During this period the presence of sweating on other parts of the trunk and limbs was ascertained by measuring the galvanic skin resistance and testing by the iodine-starch method (Wada and Takagaki, 1948; Wada, 1950).

Ichthyosis.—The transepidermal water loss was measured after inhibiting sweating with 2% poldine under occlusion in nine subjects. Seven had the sex-linked form of ichthyosis and two the autosomal dominant form (Wells, 1966).

Psoriasis and Erythroderma.—The transepidermal water loss was measured in areas of skin affected by localized psoriasis in eight patients and in six cases of erythroderma, five of the latter were psoriatics. In all these cases the skin was painted with 1% poldine and allowed to dry for 30 minutes. No further application was made to the skin. The next day the transepidermal water loss was estimated. In order to avoid irritating the skin polyethylene occlusion and adhesive plaster were not used. In four cases repeated measurements were made at various stages of activity of the disease. In two cases the water loss was measured in areas which had not been treated with poldine and compared with the treated areas. A total of 16 measurements of skin water loss were made in all. Owing to the enormous skin water loss that was found in these cases a slight variation was necessary. In normal subjects, after the transepidermal water loss was measured, no measurable condensation was found to take place in the apparatus. Appreciable condensation on the walls of the apparatus was found, however, to have occurred after measuring the skin water loss in cases of psoriasis and erythroderma. To allow for this the following method was used:

The apparatus was as usual washed out with dry air before starting. The collecting chamber was then placed on the abdomen and straight away the water given off by the skin was collected. A steady state as indicated by the humidity transducer was reached in one to two minutes. As soon as the 30-minute collecting period had come to an end, the collecting chamber was removed from the skin and the air flow turned off. An airtight base was fitted to the collecting chamber and the apparatus reconnected to another water tap. Dry air flow was then passed through the apparatus for 30 minutes, or until no further moisture could be obtained. (The monitoring of the humidity transducer was found to be a useful guide to the rate of drying of the apparatus.) The weight of water thus collected from the apparatus was added to that obtained during the 30-minute skin water loss estimation.

Normal Skin Areas in Eczema and Psoriasis.—After inhibiting sweating with poldine under occlusion the transepidermal water loss was measured in areas of normal skin in patients with eczema and psoriasis.

Results

Normal Transepidermal Water Loss

The water loss by diffusion through normal skin was remarkably small. This was in spite of a very low ambient humidity and free air movement.

The mean transepidermal water loss in 47 normal subjects was 0.35 (S.D. 0.09) mg./sq. cm./hr. (skin temperature 32–36° C., relative humidity 2–5%, air speed 23–25 mm./sec.).

No significant correlation was found with age (39 subjects). (Correlation coefficient, -0.22 ; 95% confidence limits for the population correlation coefficient are -0.5 to $+0.13$.)

The "maximal" possible whole-body daily transepidermal water loss may be estimated from the measured rate of transepidermal loss (mg./sq. cm./24 hr.) and the total surface area (Du Bois formula). The results in 29 patients are seen in Fig. 3. The ambient humidity in the collecting chamber was very dry (2–5% relative humidity); the results are therefore higher than would be expected under ordinary room conditions, since the rate of transepidermal water loss decreases with rising ambient humidity. The total actual daily loss will depend on the humidity of the air in direct contact with the skin, which depends on room humidity, the presence of sweating, and the effect of clothing.

The transepidermal water loss also increases with rising skin temperature. The temperatures during the measurements were those of "covered skin," the skin temperature under the collecting chamber being 1–2° C. higher than the adjacent uncovered areas. The transepidermal water loss from the calf and thigh was measured in a few cases, and, though significantly raised, was of the same order as that from the abdomen.

The transepidermal water loss from the calf in five subjects was 0.6 (S.D. 0.12) mg./sq. cm./hr. ($t=4.6$, $P<0.01$). The transepidermal water loss from the thigh in seven subjects was 0.46 (S.D. 0.14) mg./sq. cm./hr. ($t=2.3$, $0.05>P>0.01$).

The mean estimated daily transepidermal water loss in 19 normal subjects was 151 (S.D. 44.2) ml./day, range 63–280 ml./day.

The heat loss by evaporation of 1,000 ml. of water is 580 kilocalories. The daily heat loss from evaporation of the normal maximal transepidermal water loss is therefore 87 (S.D. 25) kcal.

Ichthyosis

The results are set out in Fig. 1. The mean transepidermal water loss was found to be 0.71 (S.D. 0.29) mg./sq. cm./hr.

FIG. 1.—Ichthyosis. Transepidermal water loss compared with normal.

(skin temperature 32–35° C., relative humidity 2–12%). This was highly significantly greater than normal, though in three cases the transepidermal loss was normal ($t=3.9$, $P<0.01$).

On routine testing of sweating from the rest of the trunk and limbs the findings were of some interest. Sweating from the trunk and limbs was strikingly less than normal, while sweating from the areas of "constant emotive sweating" was normal in eight of the nine cases. These areas of emotional sweating are the axillae, face, palms, soles (Kuno, 1956), and over the distal dorsal phalanges and back of the interdigital webs (Grice and Bettley, 1966).

Only one patient had tylosis of the palms and soles (Case 9, Fig. 1), and she had normal palmar and plantar sweating. One patient (Case 6, aged 35) had remarkably little palmar and periungual sweating.

Sweating could not be detected on the trunk and limbs (apart from the emotive areas) in eight of the nine cases (Nos. 1–7 and 9). The room temperature and relative humidity were 20–23.5° C. and 52–66% respectively. The skin temperatures were 34–35° C.

To exclude the possibility that slight sweating was taking place in areas of skin in which sweating could not be detected by the iodine-starch or galvanic skin resistance test, six further measurements of skin water loss were made. Skin untreated with poldine was compared in the same patients with sweat-inhibited areas. The water loss was found to be the same in the two areas. On heating, sweating occurred from the trunk and limbs.

The maximal whole-body daily transepidermal water loss in six subjects was estimated (see Fig. 3). The mean was 348 (S.D. 124) ml./day (skin temperature 32–35° C., relative humidity 2–12%). The maximal daily whole-body transepidermal water loss was therefore about double that of normal subjects. Under ordinary environmental conditions the actual transepidermal water loss will probably be nearer the maximal than in the normal subjects. The reasons for this are, firstly, that in the cases with ichthyosis there was a higher ambient humidity (resulting from the increased skin water loss) in the collecting chamber, and, secondly, under normal conditions, as sweating is depressed in ichthyotics, the ambient humidity over the skin

FIG. 2.—Psoriasis and erythroderma. Transepidermal water loss compared with normal. Case 1: B, 7 days after A. Case 4: D, 12 days after C; E, 22 days after C. Case 8: G, 10 days after F; H, 12 days after F; I, 12 days after F, different site from H. Case 9: K, same day, different site, no pretreatment with sweat-depressing agent.

is likely to be less than in a normal person. In normal subjects the relative humidity under a shirt has been shown (Mellanby, 1932) to vary widely between 20 and 70%.

Psoriasis and Erythroderma

The transepidermal water loss in psoriasis and erythroderma was greatly increased. This was in spite of high ambient humidities which resulted from the high skin water loss. The highest ambient humidities were produced in the cases with the greatest skin water loss (see Fig. 2).

The mean transepidermal water loss over patches of psoriasis in eight patients was 5.37 (S.D. 2.6) mg./sq. cm./hr. (skin temperature 34–35° C., relative humidity 10–70%).

When the psoriasis spread and became generalized in one patient with very active pustular lesions (Case 4, Fig. 2) the transepidermal water loss (D) was found to be little changed from the previous measurement over a patch (C). Three weeks later, when the eruption was still generalized but less active, the transepidermal water loss had decreased from 7.7 to 3.2 mg./sq. cm./hr. (Case 4, D and E).

Erythroderma

The mean transepidermal water loss of nine measurements in six cases was 4.96 (S.D. 2.5) mg./sq. cm./hr. (skin temperature 32–35.5° C., relative humidity 20–70%).

The water loss from skin untreated with poldine (Fig. 2, Case 8 I, Case 9 K) was compared in two patients with the transepidermal water loss after sweat inhibition. The water loss can be seen to be similar.

The mean daily whole-body transepidermal water loss in subjects with erythroderma, estimated from six measurements taken at different stages of the disease (see Fig. 3) was 2,158

The total daily loss of heat from evaporation of this transepidermal water is estimated to be 1,252 (S.D. 591) kcal./day.

Transepidermal Water Loss in Normal Skin Areas in Patients with Eczema and Psoriasis

In 17 cases of eczema the mean transepidermal water loss in unaffected skin areas which had never been affected was 0.55 (S.D. 0.15) mg./sq. cm./hr. (skin temperature 32–36° C., relative humidity 5–10%).

The transepidermal water loss is highly significantly greater in areas of normal skin in patients with eczema compared with normal subjects ($t=5.2$, $P<0.01$). The mean transepidermal water loss in unaffected skin areas in 16 cases of psoriasis was 0.41 (S.D. 0.16) mg./sq. cm./hr. (skin temperature 32.5–35° C., relative humidity 5–8%). This was not significantly different from normal ($t=1.8$, $P>0.05$).

Discussion

The present studies show that the loss of water by diffusion through normal skin is remarkably small, 0.35 (S.D. 0.09) mg./sq. cm./hr. This is well known, though in most previous studies of skin water loss sweating was not inhibited. Pinson (1942) found, under conditions similar to those in the present investigation, that the transepidermal water loss was 0.58–1.58 mg./sq. cm./hr. He, however, used the iontophoresis of formalin to inhibit sweating, and iontophoresis may increase the skin permeability (Rothman, 1954). Pinson's results then would be higher than expected. The rate of water diffusion through excised trunk skin is said to be 0.25–0.58 mg./sq. cm./hr. (Mali, 1956; Onken and Moyer, 1963).

In spite of a very low ambient humidity, free air flow, and skin temperature similar to that under clothes, the estimated whole-body daily transepidermal water loss was only 151 (S.D. 44.2) ml./day.

A study of skin affected by psoriasis and erythroderma has shown the transepidermal water loss to be enormously increased; this in spite of very high ambient humidities comparable with those of the clothed skin. This increase of skin water loss, which amounted to over 20 times normal in some cases, was in spite of sweating having been inhibited. A ten-fold increase in the skin water loss was reported in psoriasis and exfoliative dermatitis (Felsher and Rothman, 1945), and a sixteenfold increase in burns on the third day (Cohen, 1966). The apparatus used by Felsher and Rothman was a glass collecting chamber in which was suspended a bag filled with calcium chloride.

The daily whole-body transepidermal water loss in erythroderma was estimated to amount to 2,518 (S.D. 1,019) ml./day, being therefore 10 to 20 times normal. The daily insensible skin water loss in erythroderma, measured by weighing patients, was found by Zoon and Mali (1957) to be 1,183 to 2,370 ml./day. This included weight loss from sweating. Sweating is, however, known to be depressed in erythroderma, eczema (Cormia and Kuykendall, 1955), and psoriasis (Suskind, 1954). The total daily skin water loss in erythroderma may therefore well consist largely of the transepidermal water loss.

Complete sweat-duct blockage persisting after heating and methacholine stimulation has been described in erythroderma (Cormia and Kuykendall, 1955) and acute psoriasis (Mitchell and Forstner, 1962). In the present investigation in two of the cases of erythroderma (due to psoriasis and Hodgkin's sarcoma) the skin water loss was found to be the same whether or not sweating had been inhibited.

On the other hand, sweating had been observed in erythroderma during heating (Fox *et al.*, 1965), and in the present investigation palmar sweating was found to be present in

FIG. 3.—Daily transepidermal water loss in normal skin, ichthyosis, and psoriatic erythroderma.

(S.D. 1,019) ml./day (skin temperature 32–36° C., relative humidity 16–72%). The transepidermal water loss is therefore about 10 to 20 times normal.

The ambient humidity in the collecting chamber was very high, the highest water loss resulting in an ambient humidity of as much as 72% (see Fig. 2). Under normal conditions, therefore, the actual daily transepidermal water loss in erythroderma patients may well be nearly as high as that estimated.

The covering of skin with ointments which form an occlusive film will obviously decrease the skin water loss, and under normal conditions there will not be such a free air flow.

pustular psoriasis after the acute anhidrotic phase of the disease. In the cases where sweat-duct blockage is not complete there may be a partial functional depression of the sweat glands.

It has been suggested that the general state of hydration of the subject might influence the amount of sweat loss (Macpherson, 1960). The large transepidermal water loss with resultant heat loss might equally well influence the amount of sweating in erythroderma.

In normal subjects palmar sweating is constantly present while they are awake (Kuno, 1956); in three patients with erythroderma whose palmar skin was not affected, and had never been affected, palmar sweating we found was greatly depressed.

The increased heat loss, which may amount to 1,252 (S.D. 591) kcal./day from vaporization of the large transepidermal water loss through the skin in erythroderma may also explain the hypothermia which occurs in some of these patients. Mali (1952) showed that there is also increased heat loss from the raised skin temperatures which he found in 83% of the patients with erythroderma. The skin temperatures were about 1° C. higher than normal. In one patient of the present series (Case 4, Fig. 2) with acute pustular psoriasis that was becoming generalized, the skin temperature was 1° C. higher in the affected skin as compared with the adjacent unaffected skin. The heat loss by radiation from 1° C. rise of skin temperature over the whole skin surface is known to be 360 kcal./day (Keele and Neil, 1965).

The raised metabolic rates found in patients with erythroderma (basal metabolic rates +6% to +119%) could be explained by the increased heat loss in these conditions (Mali, 1952). The ¹³¹I excretion has been found to be normal (Magnusson, 1960; Fox *et al.*, 1965).

In the present investigation the transepidermal water loss in ichthyosis was found to be approximately double that of normal subjects. In two of these cases there was a history of atopic eczema (Cases 5 and 9), but both patients were free from eczema at the time of testing (for 23 and 40 years). Trunk and limb sweating was found to be depressed, as reported previously (Wells, 1966), but sweating from the palms, soles, and periungual regions was found to be normal in eight of the nine cases. Sweating from the trunk was present during heating, and in warm climates with increased sweating all the patients noticed an improvement of their skin. The comparative sparing of flexures found in ichthyosis vulgaris could perhaps be associated with the diminution of sweat or transepidermal water evaporation at these sites.

Summary

The transepidermal water loss from the skin, due to the passive diffusion of water through the epidermis, was found to be greatly increased in psoriasis and erythroderma, and slightly but highly significantly increased in ichthyosis.

Improvement of the skin condition showed a corresponding decrease in the water loss.

In 47 normal subjects the mean transepidermal water loss from the abdomen was extremely small: 0.35 (S.D. 0.09) mg./sq. cm./hr. (skin temperature 32–36° C., relative humidity

2–5%); the maximal loss from the whole body in a dry ambient humidity amounting to only 151 (S.D. 44.2) ml./day.

No significant correlation was found with age. A slight but significant regional variation was observed, the loss from the calf and thigh being greater than from the abdomen.

In patches of psoriasis the transepidermal water loss could be as much as 20 times that of normal, 5.37 (S.D. 2.6) mg./sq. cm./hr. (relative humidity 10–70%).

In ichthyosis the loss was about twice the normal, and sweating from the trunk and limbs was markedly reduced, though sweating from the constantly sweating emotional areas (palms, soles, axillae, dorsal distal phalanges, and face) was normal in eight of the nine cases.

In erythroderma the daily transepidermal water loss was about 14 times normal and could be as high as 2,158 (S.D. 1,019) ml./day.

It is suggested the loss of heat by vaporization of the increased transepidermal water loss could explain the hypothermia and increased basal metabolic rates which occur in some cases of erythroderma.

We thank Dr. R. S. Wells for kindly referring his patients; Dr. R. H. Meara for allowing us to study patients under his care; Mr. I. D. Hill, of the Medical Research Council Statistical Research Unit, for his help; the Medical Research Council for a grant to K. A. G.; and the Clinical Research Committee for granting facilities to undertake this work. We also thank the illustration department of the Middlesex Hospital. Poldine methosulphate (Nacton) was kindly provided by Beecham Research Laboratories Ltd.

This paper forms part of a thesis which has been submitted for the M.D. thesis by K. A. G.

Intracardiac Pacing as Emergency Treatment in Adams-Stokes Syndrome

GUNNAR BAY,* M.D.; EGIL SIVERTSEN,* M.D.

Brit. med. J., 1967, 4, 199-200

In most cases of atrioventricular block with Adams-Stokes attacks the application of either an endocardial or an epicardial electrode for artificial pacing can be performed in the operating-theatre with all necessary equipment available. In some cases, however, the situation is more dramatic: electrical pacing may be necessary without any delay, and it may be impossible to transfer the patient to the operating-theatre or an x-ray laboratory with TV equipment. In such emergency cases we have used a technique which renders it possible to introduce an endocardial pacemaker electrode by means of very simple equipment, and the method which we have applied in 27 cases has proved to be safe and reliable. The principle is to use the pacemaker electrode for picking up the electrocardiogram from the heart cavities. As the electrocardiogram from the atrium

pacemaking is established. The electric defibrillator and the external pacemaker are held in readiness.

Materials

From September 1965 to April 1967 indications for intracardiac pacing were found in 62 patients. Twenty-seven of these were critically ill with repetitive Adams-Stokes attacks, and the emergency introduction of an endocardial pacemaker electrode by the described technique was therefore attempted (see Table). Fifteen of these had acute myocardial infarction. In 21 the electrode was successfully placed in the right ventricle, and effective stimulation of the heart was obtained in all of them. In one patient (Case 1) with sinoatrial block the tip

FIG. 1.—A, subcutaneous indifferent electrode. B, soft, flexible intracardiac electrode. C, external pacemaker (Elema-Schönander).

as well as from the ventricle is highly characteristic, the electrocardiographic pattern can easily be used as guide for a correct introduction into the right ventricle without the aid of fluoroscopy.

Method

Under sterile conditions and after cleansing and draping the area an incision is made over the antecubital or jugular vein. A soft flexible intracardiac electrode (Fig. 1) is introduced into the exposed vein and connected to the V terminal of an electrocardiograph by means of a clip. The electrode is then advanced to the right atrium under constant monitoring on oscilloscope or electrocardiograph. When characteristic atrial patterns are seen (Fig. 2), the patient is carefully rotated to the left lateral position to facilitate passage of the electrode through the tricuspid valve. The electrocardiographic patterns change suddenly when the electrode passes into the ventricular cavity. The atrial complexes become small, and the ventricular complexes large with the rS or QS appearance. The electrode is then advanced a further 5-6 cm. to place the tip in the apex region of the right ventricle. At this point typical contact patterns should be seen (Fig. 2). An indifferent electrode is thereafter placed subcutaneously in front of the sternum, and the two electrodes are connected to a battery-driven pacemaker. If the intracardiac electrode is in the correct position, effective stimulation of the heart is gained with an amplitude of 1-2 V.

Intravenous infusion of isoprenaline is started before beginning the procedure, and is continued until satisfactory

of the electrode did not pass into the ventricle, but effective stimulation was obtained from the right atrium. In one patient with atrioventricular block (Case 4) the typical endoventricular complexes were not registered, but, in spite of this, satisfactory stimulation was obtained. This patient died later in cardiac failure, and at necropsy the tip of the electrode was found in the coronary sinus. In four patients introduction of the electrode was unsuccessful: three (Cases 8, 24, and 25) died during the attempt, the fourth (Case 15) some hours later.

FIG. 2.—Intracavitary E.C.G.-registration during pacemaker electrode placement. Top: Registration from the right atrium and lead I. Bottom: Registration from the right ventricle with typical contact patterns.

* Ullevål Hospital, Department VIII, Oslo.

Nine of the 21 patients with effective pacing died during the hospital stay: four of them in ventricular fibrillation in spite of satisfactory pacing, and four in cardiac failure. Treatment with artificial pacemaker could be discontinued after 4 to 25 days in five patients in whom sinus rhythm returned. Indica-

tions for permanent pacemaker treatment were present in eight patients.

Discussion

Intracavitary electrocardiography has for many years been used in cardiac catheterization to determine the location of the catheter tip. The method has also been used in the daily clinical work as a supplementary method in the diagnosis of cardiac arrhythmias, utilizing a thin Teflon-coated stainless-steel wire with a platinum tip (Vogel *et al.*, 1964; Nutter and Kelser, 1965; Sivertssen, 1967). This electrode has been used for temporary pacing of the heart (Harris *et al.*, 1965; Kimball and Killip, 1965).

Introduction of the intracardiac pacemaker electrode should preferably be performed under fluoroscopy and TV monitoring. In urgent situations when such equipment is not available, the described method can be used as a bedside procedure. The technique is easy to perform, may be applied quickly, and does not require other special equipment than that usually available in most medical departments. The identification of the intracardiac electrocardiographic patterns is not too difficult in most cases, but extremely slow heart rates may cause a problem because so few ventricular patterns are seen. It is extremely important to make sure that the recorder and other instruments connected to the patient are properly earthed. Leaking of electric current through the intracavitary electrode may provoke ventricular fibrillation.

The electrode may be introduced in the vein percutaneously in patients with large antecubital or jugular veins. In most cases, however, a cut down on the vein is necessary. We have tried thin Teflon-coated steel-wire electrodes designed for intracavitary electrocardiographic diagnosis, but have not obtained effective stimulation. It is of great importance that the electrode is soft and flexible because of the danger of perforating the ventricular wall during the introduction.

In eight patients artificial pacemaking had to be continued as a permanent treatment. In these cases the external end of the electrode after thorough cleansing was taken out through an incision in the subclavian vein and then led subcutaneously to the right abdominal region, where it was attached to an implanted pacemaker. Infection or thromboembolic complications have not occurred. In most cases the electrode was introduced into an antecubital vein, usually the basilic vein of the right arm. When the electrode was firmly fixed in the elbow region, the patient was able to move the arm freely without displacement of the electrode. In one patient the electrode was pulled out accidentally during sleep. Usually the external jugular vein is used for introduction of pacemaker electrodes for permanent treatment. In urgent situations, however, it may be difficult to find a suitable vein in the neck.

The intracardiac electrode has been removed without difficulty even after 25 days, when further treatment with the artificial pacemaker was not indicated.

Summary

A simple and effective bedside method is presented for transvenous intracardiac pacing in urgent clinical situations when fluoroscopic equipment is not available. The method permits intracardiac electrode placement using the intracavitary electrocardiogram picked up by the pacemaker electrode as a guide.

Successful placement of the electrode was achieved by this method in 21 out of 27 critically ill patients with repetitive Adams-Stokes attacks.

Oxygen Concentrations in Tents and Incubators in Paediatric Practice

HAMISH SIMPSON,* M.B., M.R.C.P.ED., D.C.H.; DOREEN J. RUSSELL,* S.R.C.N.

Brit. med. J., 1967, 4, 201-203

Oxygen therapy is a common requirement in paediatric practice and is generally administered in commercially available tents or incubators. Batson and Young (1958) stated that they were "unable to create and maintain therapeutic concentrations of oxygen in tents," and it is therefore surprising that alternative, more efficient, methods of administering oxygen (Burgess and Burgess, 1932; Morrison, 1955; Batson and Young, 1958; Godfrey, 1959) have not found wider acceptance.

Oxygen concentrations of at least 60% are claimed for many of their products by the manufacturers of tents and incubators, tested under laboratory conditions. As an inspired oxygen concentration of 40% does not invariably relieve hypoxia in infants with acute respiratory failure (Downes and Striker, 1966; Simpson and Flenley, 1967), it seems particularly relevant to report the oxygen concentrations attainable in present-day tents and incubators during clinical use.

Tents and Incubators

Six tents (Table I) and four models of incubator (Table II) were studied. Tents 1 (Air-Shields Type D Croupette), 2 (Air-

(c) Flushing at 20 l./min. for 20 minutes as recommended; thereafter readings after 20 minutes at given flow rate.

Shields Universal Croupette), and 3 (Oxygenaire Humidaire Tent) are used for infants and young children, whereas Tents 4 (Oxygenaire Universal Tent) and 5 (Oxygenaire Mark V Tent) are more suitable for older children who may find the others too confined. A high humidity is provided by each except Tent 4,

* Department of Child Life and Health, University of Edinburgh, and the Royal Hospital for Sick Children, Edinburgh.

but coolness for fevered children is obtainable in all. Tent 6 (Oxygenaire Venturi Head Tent) is designed to provide controlled oxygen therapy to adults with chronic respiratory insufficiency, during exacerbations of infection.

The incubators (Table II) are used in the neonatal period and provide high humidity and accurate temperature control in addition to oxygen. The Air-Shields Intensive-Care Isolette and the Oxygenaire New Incubator are fitted with a device to limit oxygen concentration to 40% or less, though higher concentrations are possible when necessary. The Oxygenaire Series III Incubator is included in this study as it is still widely used. The Oxygenaire Mark III Portable Incubator is generally used to transport newborn infants from home to hospital, thereby minimizing the risk of hypothermia and/or hypoxia during the journey.

TABLE II.—Oxygen Concentrations in Incubators Under Ideal Clinical Conditions

Incubator Model	No. of Observations	Oxygen Flow Rate (l./min.)	Actual Concentration at Child's Mouth (%)		Possible Oxygen Concentration Claimed (%)

Method

The tents and incubators were tested under normal working conditions. In Tents 1 to 4 the patients were infants or young children believed on clinical grounds to require oxygen therapy, whereas healthy children co-operated in testing Tents 5 and 6. The canopies of Tents 1 to 5 were carefully tucked in to avoid leakage, and all zips were tightly closed. Each tent was then flushed as recommended (usually 10 litres of oxygen per minute for 30 minutes) and the oxygen flow rate subsequently adjusted to 2, 4, 6, 8, 10, and 20 l./min. The oxygen flow meters used were supplied by the British Oxygen Company and are calibrated from 0 to 10 l./min. A dual outlet regulator was used to provide flow rates of 20 l./min. Samples of inspired gas were taken from within 1 in. (2.5 cm.) of the child's mouth after 20 minutes at each flow rate into 100-ml. lubricated glass syringes via stiff rubber tubing introduced through a small aperture in each tent. In this way samples were obtained under ideal clinical conditions. Tent 6 did not require flushing, and was sampled at oxygen flow rates of 2, 4, and 6 l./min.

Tents 1 to 4 were also sampled at random on numerous occasions. These tents were invariably flushed before initial usage, but routine refushing after feeding or other interference was often omitted.

The incubators were tested during use without previous flushing, every precaution being taken to avoid leakage. The oxygen concentration of gas samples was determined by a

Tent 4 (Fig. 4). The mean oxygen concentrations, ideal and random, in Tents 1 to 4 at oxygen flow rates of 10 l./min. are shown in Fig. 5. Oxygen concentrations greater than 50% are invariably attained in Tent 3.

Table II shows the oxygen concentrations measured in incubators and relates them to their manufacturers' recommendations.

FIG. 1.—Concentration of oxygen (± 1 S.D.) achieved in Air-Shields Type D Croupette in relation to flow rate of oxygen (random measurements). FIG. 2.—Concentration of oxygen (± 1 S.D.) achieved in Air-Shields Universal Croupette in relation to flow rate of oxygen (random measurements). FIG. 3.—Concentration of oxygen (± 1 S.D.) achieved in Oxypaire Humidaire Tent in relation to flow rate of oxygen (random measurements). FIG. 4.—Concentration of oxygen (± 1 S.D.) achieved in Oxypaire Universal Tent in relation to flow rate of oxygen (random measurements).

D.C.L. 101 paramagnetic oxygen analyser calibrated with air and nitrogen (Nunn *et al.*, 1964).

Results

The oxygen concentrations attained in tents under ideal clinical conditions are shown in Table I. An oxygen concentration exceeding 50% was attained in Tents 1, 3, 4, and 5 at a flow rate of 10 l./min., whereas 31% was the highest concentration attained in Tent 2 at a similar flow rate. The oxygen concentrations in Tents 1, 3, and 6 are close to those claimed possible by their manufacturers, while the levels in Tent 5 are similar to those published by Freedman (1964).

The results of random sampling (Tents 1 to 4) are shown in Figs. 1-4. When Tent 1 is used as recommended with the pressure gauge in the "green area" (usually 6 l./min.), oxygen concentrations of 30 to 45% are achieved (Fig. 1). Higher concentrations (by 4-6%) are possible when the icebox is covered. Similarly, higher oxygen concentrations are attained in Tent 2 when the icebox is sealed over with polyethylene (Fig. 2). This improves contact between the outer and inner ice-tanks, where leaks may be associated with considerable air indrawing due to the Venturi circulation at that point. In Tent 3 an oxygen concentration of 40% is readily achieved at a flow rate of 6 l./min. (Fig. 3), whereas a flow rate of 10 l./min. is required to produce a similar concentration in

Comment

The oxygen requirements of hypoxic children may vary greatly, and depend on the cause and severity of the hypoxia. The principles underlying rational oxygen therapy have been reviewed (Brit. med. J., 1964), and Flenley (1967) has suggested that oxygen therapy should aim to provide a partial pressure of at least 10 mm. of mercury at the cellular mitochondria.

FIG. 5.—Oxygen concentrations in Tents 1 (Air-Shields Type D Croupette), 2 (Air-Shields Universal Croupette), 3 (Oxypaire Humidaire Tent), and 4 (Oxypaire Universal Tent) at an oxygen flow rate of 10 l./min. Comparison of means of ideal and random measurements.

It is probable that in many instances an oxygen concentration of 50 volumes %—that is, the standard recommended for tents by the Committee on Public Health Relations of the New York Academy of Medicine (1950)—fulfils this condition. While this concentration of oxygen may be dangerous to premature babies, such babies are generally nursed in incubators in which special provision is made to regulate the ambient oxygen concentration to under 40% (Table II), thus minimizing the risk of retrolental fibroplasia. Furthermore, the use of high oxygen concentrations in the treatment of chronic hypoxic children with hypoventilation may produce carbon dioxide narcosis (Bruck, 1957). There is, however, little risk of precipitating respiratory depression by this means in infants with acute lower respiratory tract infections (Reynolds, 1963; Simpson and Flenley, 1967). The main use of oxygen tents and croupettes is probably in the treatment of such cases, in which an inspired oxygen concentration of 40% or more may be necessary to ensure a normal arterial oxygen tension (PO_2) (Simpson and Flenley, 1967). This requirement is most likely to be met in Tent 3 (Figs. 3 and 5), in which an oxygen concentration of 50% is attainable at a flow-rate of 10 l./min.

In chronic respiratory insufficiency in infancy and childhood the place of oxygen therapy has yet to be defined precisely, though the risks of injudicious oxygen therapy to children with cystic fibrosis of the pancreas are recognized (Bruck, 1957). There may also be a place for controlled oxygen therapy in the treatment of asthma (Schiller *et al.*, 1951). In such instances Tent 6 may be of value, though a young child, apprehensive and fighting for breath, might find it too confined. The children who helped in testing this tent (aged 7–9 years) were fully at ease within a few minutes.

The indications for oxygen therapy in the newborn have been reviewed by Tizard (1964). Incubators are generally used in this period and are seldom appropriate for infants over 2–3 months of age. The recognition that retinal damage in premature babies is related more to a high arterial oxygen tension than the ambient oxygen concentration *per se* has resulted in improved incubator design. Newer models provide an ambient oxygen concentration of less than 40% at a flow rate of 3 l./min., but can be adjusted to supply 60–70% oxygen when necessary (Table II). This is of particular importance in the treatment of infants with venous-arterial shunts, as shunted blood does not perfuse the lung alveoli. Even so, the addition of oxygen to the blood which does undergo gas exchange in the lung may improve tissue oxygenation. The danger of pulmonary epithelial damage—the Lorrain-Smith (1899) effect—from the inhalation of high oxygen concentrations is probably of importance in humans (New Engl. J. Med., 1967), and should be borne in mind whenever high concentrations of oxygen are used therapeutically for a prolonged period.

Summary

The oxygen concentrations attained in the tents described during routine paediatric use are reported. A concentration of 50–60% is most readily attained in the Humidaire Tent—the most efficient of the tents described. Accurately controlled oxygen therapy in the range 40–60% is attainable in the Venturi Head Tent, which may be used in paediatric oxygen therapy. Incubators in use generally fulfil their manufacturers' specifications.

We wish to thank Professor J. O. Forfar, Dr. J. W. Ferguson, Dr. D. C. Flenley, and Dr. D. G. Barr for their advice and helpful criticism of this paper. We are also grateful to Air-Shields (U.K.) Ltd. and Oxygenaire Ltd. for their helpful co-operation throughout this study.

Requests for reprints should be addressed to Dr. H. Simpson, Department of Child Life and Health, 17 Hatton Place, Edinburgh 9.

ADDENDUM.—Since this paper has been prepared the canopy of Tent 2 (Air-Shields Universal Croupette) has been modified slightly. As a result there is now no distortion of the oxygen inlets to the tent. This allows closer apposition of the outer and inner tanks of the icebox than had previously been possible. On retesting this Croupette with the "new" canopy, an oxygen concentration of 45% was obtained after one hour at a flow rate of 10 l./min., under ideal clinical conditions. The provision of a spring-loaded clip between the outer and inner tanks of the icebox in future models of this Croupette may further minimize the possibility of leakage.

Ulcerative Colitis in the Tropics

H. K. CHUTTANI,* M.D.; S. P. NIGAM,† M.D.; S. K. SAMA,‡ M.D.; P. C. DHANDA,§ F.R.C.P.
P. S. GUPTA,|| M.D.

Brit. med. J., 1967, 4, 204-207

Ulcerative colitis as a separate entity was first described by Wilks and Moxan (1875). Idiopathic ulcerative colitis has been defined as an acute and chronic inflammatory and ulcerative disease of the rectum and colon of unknown aetiology (Kirsner, 1959). Many reports on various aspects of the disease have appeared in the Western literature (Bargen, 1930; Felsen and Gorenberg, 1936; Palmer, 1948; Kirsner *et al.*, 1957; Kirsner and Goldgraber, 1960; Edwards and Truelove, 1963, 1964).

However, there has been very little documented evidence of this disease from tropical countries, and it is thought to be essentially a disease of temperate zones (Melrose, 1955). Almost 30 years ago Chopra and Ray (1939), from the School of Tropical Medicine, Calcutta, reported 120 cases of nonspecific ulcerative colitis. The clinical description and investigations leave little doubt that these were cases of this disease, as specific infections were effectively excluded. It is surprising that this report has gone unnoticed in the subsequent literature, and the impression has continued to persist that nonspecific ulcerative colitis is rare in the tropics. There were three important reasons why nonspecific ulcerative colitis was not often diagnosed: lack of facilities for precise diagnosis of dysenteric disorders; scarcity of antibacterial drugs by which a therapeutic test could be used to distinguish between recurrent specific infections and ulcerative colitis; and lack of the long-term observation of patients which is of such great help in making a diagnosis of this condition. This situation is gradually becoming corrected, and reports on nonspecific ulcerative colitis in the tropics have appeared in recent years (Pasricha *et al.*, 1958; Tandon *et al.*, 1965).

The present study had a threefold objective—namely, to assess the magnitude of the disease in this region, to compare the pattern with that reported in the West, and to emphasize the difficulties associated with the diagnosis of nonspecific ulcerative colitis due to the high prevalence of specific infections of the colon in the tropics.

Material and Methods

(1) A questionnaire was sent to the leading hospitals in different parts of the country for information regarding admission of cases of nonspecific ulcerative colitis during the period 1956-60. The inquiry covered the total number of admissions each year, the number of yearly medical admissions, and the number of ulcerative colitis cases admitted annually. The information received was analysed.

(2) Forty-six patients with ulcerative colitis were studied in detail. The diagnosis of ulcerative colitis was made on the basis of a clinical history of chronic dysentery not responding to adequate specific therapy, nonisolation of bacterial, protozoal, and helminthic pathogens on repeated smear and culture

examinations, and on sigmoidoscopic, radiological, and histological evidence of the disease.

(3) Three fresh stool specimens and a rectal swab taken during sigmoidoscopy were examined by means of saline and iodine preparations to exclude amoebic infection. Stool cultures for pathogenic bacteria were done on three consecutive days by a standard technique.

(4) The sigmoidoscopic findings were graded according to the classification of Matts (1961). Normal was taken as grade 1; mild granularity of the mucosa with mild contact bleeding as grade 2; marked granularity with oedema of mucosa, marked fragility with contact, and spontaneous bleeding as grade 3; and severe ulcerations of the mucosa with haemorrhage and/or pseudopolypoidosis as grade 4.

(5) The histological changes in the colonic biopsy were also graded (Matts, 1961): normal as grade 1; some infiltration of the mucosa, or lamina propria, with either round cells or polymorphs as grade 2; marked cellular infiltration of the lamina propria and submucosa as grade 3; the presence of crypt abscesses with marked infiltration of all the layers of the mucosa as grade 4; and ulceration, erosion, and necrosis of the mucosa with cellular infiltration of some or all of its layers as grade 5.

(6) Barium-enema examination was done in 38 patients. The extent of the disease was analysed and alterations in the radiological patterns of the colon were recorded.

Results

Admission Rate.—Information obtained from different hospitals in various cities of the country was analysed (Table I). It was observed that the admission rate in different hospitals varied from 3.6 to 26.1 cases per 10,000 hospital admissions. For medical cases alone the rate varied from 8.3 to 89.1 per 10,000 admissions. The overall admission rate came to 28.3 cases per 10,000 medical admissions and 9.4 cases per 10,000 total hospital admissions.

TABLE I.—Admission rate of Ulcerative Colitis in Various Hospitals

Name of City	Average No. of Cases per Year	Average Admissions per Year		Rate per 10,000 Admissions	
		Medical	Total	Medical Wards	Whole Hospital
(1) Calcutta ..	11.5	1,295	—	89.1	—
(2) Bombay ..	73	9,949	27,933	73.35	26.13
(3) New Delhi ..	48	17,079	57,810	41.5	10.41
(4) Amritsar ..	17	3,013	23,034	56.42	7.38
(5) Vellore ..	10.5	3,066	13,565	34.26	7.74
(6) Madras ..	16.5	18,744	37,118	8.8	4.44
(7) Gwalior ..	2.5	2,866	—	8.37	—
(8) Ahmedabad ..	8.55	10,241	23,358	8.3	3.65
Total ..	187.5	66,253	182,818	28.3	9.4

Clinical Profile.—About three-quarters of the cases were in the third and fourth decades, though the disease was seen in all age groups. The paediatric age group was not included in the study (Table II). The mean age at onset was 31.5 years for men and 25.3 years for women. The minimum age at onset was 9 years and the maximum age 56 years. Males were affected more often than females, the ratio being 2.3:1. The average duration of symptoms previous to the first examination was 3.2

years. The majority of patients came with symptoms of less than four years' standing. Most of the cases occurred in poor socio-economic groups. A family history of the disease was present in one case. Various factors incriminated by patients as precipitating an attack of the disease or aggravating the symptoms were milk in five cases, emotional disturbances in five, pregnancy in one, and respiratory infection in one. The symptoms and physical signs of these patients were carefully recorded and analysed (Table III). Loose motions with blood and mucus were the presenting symptoms in all cases. Abdominal pain and flatulence were present in most of the patients. General symptoms of the disease were less marked. On the basis of symptomatology (Truelove, 1956) 12 cases were graded as severe, 18 as moderate, and 16 as mild.

TABLE II.—Age and Sex Distribution

Age Group	Total Cases	Male	Female
12-20 years	6	2	4
21-30 "	8	8	—
31-40 "	24	16	8
41-50 "	5	4	1
51-60 "	2	1	1
61+ "	1	1	—
Total	46	32	14

TABLE III.—Clinical Features of Ulcerative Colitis

Symptoms	No. of Cases	Physical Signs	No. of Cases
Loose motions with blood and mucus	46	Abdominal tenderness ..	38
Frequency of stools ..	46	Pallor	26
Flatulence	36	Palpable liver	10
Pain abdomen (diffuse) ..	35	Hypovitaminosis B	10

Loss of weight	15	Clubbing	2
Fever	13	Palpable spleen	1
Anorexia	7		
Arthralgia	6		
Vomiting	3		
Rectal itching	3		

Complications.—Local complications were common. Pseudopolypoid (Fig. 1) was observed in seven, severe haemorrhage in two, perforation in one, pararectal abscess in one, fissure-in-ano in one, and haemorrhoids in four cases. Systemic complications were encountered in only two patients, who suffered from thrombophlebitis and arthritis respectively. The arthritis involved metatarsophalangeal, hip, knee, and ankle joints. The Rose-Waaler test was negative and the serum uric acid level was normal in this case. Four patients died during the period of

study, one from perforation, one from uncontrolled haemorrhage, one during the postoperative period after resection of the colon and ileostomy, and the fourth from fulminating disease not responding to treatment.

Sigmoidoscopic Findings.—On sigmoidoscopic examination all cases had varying degrees of abnormality. Ten patients had severe or grade 4 changes, 20 moderate or grade 3, and 16 mild or grade 2 (Matts, 1961). Pseudopolypoid was seen in three cases with severe changes.

Histological Findings.—Colonic mucosal biopsy was done in 32 cases. Severe changes (grades 4 and 5) were observed in 13 cases, moderate changes (grade 3) in 11, and mild (grade 2) changes in eight. No patient had normal (grade 1) biopsy. Cryptitis and crypt abscesses were seen in 13 cases (Fig. 2).

FIG. 2.—Rectal mucosa showing glandular hyperplasia with heavy mononuclear infiltration in the lamina propria and crypt abscess.

Radiological Findings.—Barium enema was done in 38 patients (Fig. 3). Irritability of the colon, oedema, and loss of haustration were the early and most important radiological findings in the majority of the cases. Radiological evidence of gross ulceration was seen in 11, narrowing of the lumen in 10, lead-pipe deformity in six, pseudopolypoid in six, and dilatation of the lumen of the bowel in four. The extent of the disease as seen by barium enema was analysed (Table IV). In

FIG. 1.—Gross appearance of colonic mucosa showing extensive ulceration and a number of pseudopolypi (resected specimen).

FIG. 3.—Representative radiological finding in a patient with extensive ulcerative colitis showing ragged serrations, pseudopolypoid, and narrowing of the lumen of the descending colon.

about half the cases the disease extended from the rectum to the splenic flexure. Six patients had normal radiological appearances. The disease in these cases was limited to the rectum and rectosigmoid regions only.

Discussion

The information obtained from the leading hospitals in different parts of the country revealed marked variations in the admission rate of cases of ulcerative colitis. From these figures (Table I) it would be wrong to assume that there is such an extreme variation in the prevalence of this disease. These differences are likely to be due to variations in the type of patient visiting the hospital, in the degree of interest that the attending physicians have in the disease, in the facilities available for diagnosis, and in the criteria employed for the diagnosis of ulcerative colitis. As these were not uniform it is not possible to draw any firm conclusion about the relative frequency of the disease and the factors responsible for regional differences. For this, one would need a planned prospective study.

Similar observations made in Britain (Melrose, 1955) revealed a frequency varying from 2 to 20 per 10,000 hospital admissions in different regions. Hospitals in Scotland had lower figures than those in England. The overall admission rate for ulcerative colitis from our data is 9.4 cases per 10,000 hospital admissions. This is not very different from the reported admission rate of 10 cases per 10,000 hospital admissions in the United Kingdom. Comparable figures for U.S.A. are 50–100, for Switzerland six, for New Zealand 0.55, and for Norway 5 per 10,000 admissions (Bebchuk *et al.*, 1961). One can safely conclude that ulcerative colitis is not a rare disease in tropical regions of India. Therefore early differentiation of cases of ulcerative colitis from specific dysenteries in the tropics is of importance in view of its high mortality and morbidity compared with what occurs in the specific dysenteries (Craig, 1947).

There was no significant difference in the age distribution and duration of symptoms when compared with Western reports (Bacon, 1958; Sloan *et al.*, 1950; Edwards and Truelove, 1963, 1964). Males were affected more often than females, while in Western series they are either equal or the females predominate (Sloan *et al.*, 1950; Edwards and Truelove, 1963, 1964). The smaller number of females in this series may be partly due to the fact that the number of women admitted to hospital is much lower than that of men.

Complications of ulcerative colitis may either be local in and around the large bowel or be systemic, affecting distant parts of the body. In all, complications were encountered in 12 cases (26%). This figure is on the low side compared with the Western reports of 31 to 40% (Rankin *et al.*, 1932; Ricketts and Palmer, 1946; Dennis and Karlson, 1952). Except for one case of arthritis and one case of thrombophlebitis, systemic complications were conspicuously absent. Sloan *et al.* (1950) and Edwards and Truelove (1964) recorded arthritis in 7.7 and 5.6% cases respectively in their series. In the present series there was no case of erythema nodosum, pyoderma gangrenosum and other skin rashes, eye lesions, ankylosing spondylitis, oral moniliasis, hepatitis, pulmonary embolism, or renal complications. Local complications such as pseudopolypoidosis, massive haemorrhage, perforation, pararectal abscess, and anal fissure were also found less frequently in this study than in Western surveys (Sloan *et al.*, 1950; Edwards and Truelove, 1964). Acute dilatation of the colon, fibrous strictures, fistulae, and carcinoma of the colon were not encountered. Sloan *et al.* (1950) observed fibrous strictures in 11.1% of cases, perianal and

perirectal infections and fistulae in 6%, and carcinoma of the colon in 5.4%. Edwards and Truelove (1964) reported figures of 6.3%, 7.7%, 3.5%, and 1.6% for fibrous strictures, fistulae, carcinoma, and acute dilatation of the colon, respectively.

Severe abnormalities on sigmoidoscopy were found in 10 out of 46 cases. In the remaining 36 the changes were mild to moderate. Matts (1961) observed severe or grade 4 changes in 46 (36.5%) of his series of 126 patients of ulcerative colitis. Rectal biopsy showed histological abnormalities of varying grades in all cases. Severe changes (grade 5 and 4) were seen in 13 cases (40.6%). Matts (1961) reported severe changes in 50% of rectal biopsies in cases of ulcerative colitis.

On radiological examination the disease was less extensive and more often confined to the rectum, sigmoid, and descending colon. The entire colon was involved in only two cases. There was no case of backwash ileitis. Ricketts *et al.* (1948) reported extensive disease involving the whole of the colon, with or without backwash ileitis, in 30% of cases.

Thus ulcerative colitis as seen in this region appears to be a milder disease with fewer complications and less severe sigmoidoscopic and histological changes. Why the disease is milder with limited involvement of colon than that seen in the West is not apparent. Is it that the repeated infections made the colon less prone to nonspecific ulcerative colitis or is it that this is a disease of the sophisticated and our population has not reached a comparable degree of sophistication with resulting psychological stresses? Psychological stresses are thought to have a bearing on the causation of the disease (Finch and Hess, 1962; Fullerton *et al.*, 1962; Daniels *et al.*, 1962).

The diagnosis of ulcerative colitis in the tropics is more difficult than in Western countries because of the high prevalence of amoebic and bacillary dysenteries. In addition, diffuse colonic tuberculosis and lymphogranuloma venereum also create difficulty in diagnosis, because the clinical picture of chronic nonspecific ulcerative colitis is sometimes virtually indistinguishable from those conditions. Fortunately, diffuse colonic tuberculosis is rare (Glenn and Read, 1946; McColl, 1956; Virmani, 1963) and lymphogranuloma is present in only isolated areas.

Sigmoidoscopic and radiological appearances similar to those seen in ulcerative colitis have been observed in cases of proved bacillary and amoebic infections (Manson-Bahr, 1943). Cryptitis and crypt abscesses on rectal biopsy have also been seen in cases of specific dysenteries, though much less frequently. Microbiological and parasitological study may not reveal the pathogens in many cases of specific infections, especially when patients have received some antimicrobial agents before investigation. Powell and Wilmont (1966) have raised the interesting problem of ulcerative post-dysenteric colitis resulting from amoebiasis. Whether this condition is a separate entity or whether amoebic infection is associated with nonspecific ulcerative colitis is not apparent. Further study and follow-up are required to clarify this situation. There is thus distinct difficulty in the differential diagnosis of ulcerative colitis and specific infections of the colon in the tropics, and often one has to depend on therapeutic tests to exclude the latter. It has therefore been a routine in some centres, even when repeated examinations have failed to demonstrate pathogens in the stools, to give adequate antibacterial and anti-amoebic therapy in every case of the chronic dysenteric syndrome before diagnosing the case as idiopathic nonspecific ulcerative colitis.

Summary

A survey of the medical records of leading hospitals in different parts of India for the period 1955–60 revealed that ulcerative colitis is not rare in this part of the world. The admission rate in different hospitals varied from 8.3 to 89.1 cases per 10,000 hospital admissions.

Forty-six cases of ulcerative colitis were studied in detail. By comparison with Western series, ulcerative colitis as seen in this region is a milder disease with fewer complications and with less severe changes on sigmoidoscopy and rectal biopsy. The disease remains limited to the rectum, sigmoid colon, and descending colon in the majority of cases.

Owing to the high prevalence of specific infections of the colon there are difficulties associated with the diagnosis of ulcerative colitis, and these are discussed.

We are thankful to the Director-Principal of Maulana Azad Medical College and associated hospitals for permission to publish this work. We are indebted to Professor D. N. Gupta and Professor O. P. Bhardwaj for histological and radiological studies of the relevant material. We are grateful to Dr. J. B. Chatterjee, Dr. R. Subramaniam, Dr. P. Raghavan, Colonel R. D. Ayyar, Dr. R. P. Malhotra, Dr. P. Koshy, Dr. P. N. Laha, and Dr. O. P. Gupta for assisting in the collection of information regarding the admission rate of ulcerative colitis. Thanks are also due to Dr. M. C. Watsa, Medical Department, Glaxo Laboratories Private Limited, for a liberal grant to carry out this study.

Electroencephalogram and Retinal Vessels in Congenital Cyanotic Heart Disease Before and After Surgery

EVA M. KOHNER,* M.B., B.SC., M.R.C.P.; E. M. ALLEN,† M.B., B.CHIR., M.R.C.P.
 K. B. SAUNDERS,* M.D., M.R.C.P.; V. M. EMERY‡; C. PALLIS,§ D.M., F.R.C.P.

Brit. med. J., 1967, 4, 207-210

The electroencephalogram (E.E.G.) is often abnormal in patients with congenital cyanotic heart disease (Shev and Robinson, 1958; Lesny *et al.*, 1960; Fowler *et al.*, 1962; Allen *et al.*, 1967). The reason for this is unknown. The disturbance of cerebral function might be due to structural brain disease, which is commonly present (Cohen, 1960), to chronic arterial desaturation, or to decreased cerebral blood flow resulting from a high packed cell volume (P.C.V.). Many of these patients also have abnormal fundi for which the polycythaemia has been incriminated (Taussig, 1960).

We have recently had the opportunity to study the retinal and E.E.G. changes in 12 patients with congenital cyanotic heart disease both before and at various intervals after operative treatment of their cardiac defects. The data obtained may throw some light on the cause of the abnormal E.E.G.s seen in these cases.

Angiographic study of the cerebral circulation in these patients is dangerous because of their known liability to cerebral thrombosis. The retinal vessels, however, are readily accessible for repeated examination, and their response to cardiac surgery may give some indication of what is happening at the level of the cerebral vasculature.

postoperatively. Cases 1 to 9 (inclusive) were further investigated three months after the operation. In Cases 3, 12, and 9 further records were obtained at six months, 12 months, and three years respectively. Routine bipolar recordings were taken with a Kaiser 8-channel portable machine (T.R. 60), the international system of electrode placement being used.

Retinal Studies.—Retinal photographs were taken within 24 to 48 hours of the E.E.G. in all patients with the exception of one (Case 6), who was not studied, and of two (Cases 4 and 9) who had no pictures taken at three months. Case 8 was studied two weeks postoperatively as well. The pupils were dilated with 0.5% cyclopentolate and 10% phenylephrine. Retinal photographs were taken with a Zeiss fundus camera and Kodachrome II film. The disc, superior temporal, and macular areas were studied routinely. The prints were identified by code and allocated by three observers into one of four groups: normal or mildly, moderately, or severely abnormal. For purposes of grading, the following features were taken into account: degree of cyanosis of fundus, vascularity of disc, and calibre and tortuosity of retinal vessels.

Results

Retinal Changes

Preoperative.—In all the patients cyanosis gave the fundus a much darker hue than normal. The discs appeared more vascular than normal in Cases 1-4 and in Case 9. In Case 2 there was frank papilloedema (Fig. 1). In all patients both arterioles and venules were markedly dilated and tortuous. In addition there was a general increase in vascularity of the entire fundus, with many prominent small vessels. The excessive vascularization appeared to be due to normal, though dilated, arterioles and venules. These changes were most pronounced in the patients with severe or moderately severe cardiac disability. These were the patients with the highest P.C.V. (Table II).

Postoperative.—The greatest changes occurred during the first two weeks (the general condition of the patients precluded an earlier photographic assessment), and there was further improvement at three months. The fundi became much pinker (less cyanosed). Of interest was the development of "atrophic"

("albinotic") fundi in three of the patients studied (Cases 3, 7, and 9). This may have been masked preoperatively by the engorgement of the retina and choroid.

The abnormal vascularity of the disc returned to normal in most instances. In the patient with papilloedema (Case 2) there was remarkable improvement, though the disc was still not quite normal at three months (Fig. 2).

The tortuosity and dilatation of the vessels decreased at two weeks and improved further at three months. The number of small vessels appeared to be reduced.

The greatest change in the fundal appearance (Case 2) occurred in the patient who also exhibited the greatest postoperative fall in the P.C.V. (from 80 to 44%). The only patient whose fundal appearances remained unchanged at two weeks (Case 10) was found at operation to have a defect not amenable to correction. Her P.C.V. was not significantly affected by the operation.

E.E.G. Changes

(a) **Preoperative.**—Only two patients had normal records (Cases 7 and 9). In eight patients (Cases 1, 3-5, 8, and 10-12) the E.E.G. was unequivocally abnormal, showing various combinations of abnormally slow dominant rhythm, excess theta and delta activity, focal delta and sharp waves, and runs of spike and wave. The records of Cases 2 and 6 were doubtfully abnormal.

(b) **Early Postoperative.**—One record (Case 5) showed improvement: a reduction in spike and wave. This patient had been given anticonvulsant cover during the operation and was still receiving phenobarbitone. In one patient (Case 1) the record was unchanged. In the other eight patients the records had deteriorated. The deterioration usually consisted of a slower and more irregular dominant rhythm and/or increased theta and delta activity, usually bilateral.

(c) **Late Postoperative.**—Nine patients had records taken about three months after operation. Comparison with the preoperative records showed improvement in only three patients (Cases 1, 2, and 4). In these the alpha rhythm was more regular and there was a reduction of slower components. In two other patients (Cases 5 and 7) the E.E.G.s had reverted to their pre-

FIG. 1.—From a colour slide of Case 2, showing the disc area preoperatively. Note papilloedema, dilatation, and tortuosity of both arterioles and venules.

FIG. 2.—Same as Fig. 1, three months after operation. Disc margins almost normal. Dilatation and tortuosity of vessels much less.

operative pattern. In four patients (Cases 3, 6, 8, and 9) the records were worse (slower and less rhythmic alpha activity and increased theta and delta activity). Fig. 3 illustrates the changes in a typical case.

Three years after operation the E.E.G. in Case 9 showed a return to the preoperative state.

Details concerning retinal appearances, E.E.G.s, and P.C.V.s are summarized in Table II.

Discussion

All patients had abnormal retinal vessels and a cyanosed fundus before operation. The abnormalities were most severe in the patients with the highest P.C.V., but it is probable that these patients also had the most severe arterial desaturation. The postoperative improvement in the appearance of the retinal vessels was associated with a fall in the P.C.V., but the arterial saturation had also reverted towards normal. The relative importance of a low PO_2 and a high P.C.V. with increased blood viscosity in the causation of the retinal vascular changes were not ascertained in this study. Investigations of patients with hypoxia (and hypercapnoea) due to respiratory failure, a high haematocrit due to polycythaemia rubra vera, and a high plasma viscosity due to macroglobulinaemia are now in progress and may clarify this aspect of the problem.

The high incidence of abnormal E.E.G.s in congenital cyanotic heart disease has been confirmed. It is of interest that only two patients had clinical neurological abnormalities.

Case 1 had a history of past cerebral abscesses and still suffered from epilepsy. Case 2 had bilateral synergic movements ("mirror-movements") of the upper limbs and both clinical and radiological evidence of a craniovertebral anomaly.

No relation was established between the level of the P.C.V. and the degree of abnormality of the E.E.G.

The deterioration in six of the 10 E.E.G.s recorded two to three weeks postoperatively was unequivocal. One patient (Case 4) was thought to have suffered a postoperative cerebral embolus, but the other patients had been free from overt neurological complications. These early deteriorations in the E.E.G. occurred whether or not the patient had been perfused during the operation, and were often observed despite the fact that the patients had clinically improved.

Similar deterioration of the E.E.G. recorded some two weeks after surgery for congenital heart disease was reported in 16 out of 24 cases by Torres *et al.* (1959) and in 13 out of 36 cases by Fowler *et al.* (1962). Their data, however, are not strictly comparable to ours in that they refer to mixed groups, including both cyanotic and non-cyanotic cases. Torres *et al.* (1959) found no relation between the occurrence of abnormal postoperative E.E.G.s and the constancy or intermittency of the cyanosis, blood pressure readings during surgery, oxygen saturation measured during the surgical procedure, or the duration of extracorporeal circulation. Similar early and reversible deterioration in the E.E.G. was found in two "controls" who had uncomplicated cardiac operations without perfusion (resection of coarctation of the aorta and exploratory thoracotomy only). In a series of 24 children

submitted to various unspecified cardiothoracic operations Pampiglione (1965) found similar changes in the early post-operative E.E.G.s. These subsided within a week and were attributed to a metabolic response to trauma. In our patients the early deterioration lasted somewhat longer but was also usually reversible. In five of our eight patients with such early deterioration, records taken three months postoperatively had returned towards their preoperative state.

The deteriorated E.E.G.s at three months were more difficult to explain. In only two of our four patients where this occurred was any kind of explanation in fact forthcoming. One (Case 9) had a severe chest infection at the time of the record, and the other (Case 3) developed signs of congestive cardiac failure some time after the E.E.G. Though one patient (Case 6) developed unexplained ascites immediately after the operation, this had cleared by the time of the third E.E.G. We are also unable to explain why the record in Case 8 became worse. This patient had had "closed" heart surgery and had remained free from all complications four months postoperatively. A similar deterioration in the records of 9 out of 33 patients examined one to two years after surgery was found by Fowler *et al.* (1962). Long-term follow-up is obviously necessary to determine the significance of these findings.

In only three of our 10 patients having late postoperative E.E.G.s was surgical treatment of the cardiac lesion eventually followed by an improvement in the E.E.G., despite the fall in packed cell volume and the increase in oxygen saturation that resulted from the operation. In 20 out of 33 patients with abnormal preoperative E.E.G.s examined by Fowler *et al.* (1962) the record was *unchanged* one to two years after cardiac surgery. That initially abnormal records should remain abnormal for months or even years after operation is perhaps not surprising when one recalls the high incidence of microscopic abnormalities of the brain in patients with congenital heart disease (Cohen, 1960), even if not submitted to surgery. The effects of chronic hypoxia may outlast the hypoxia itself. It is not inconceivable that long-acting hypoxia may permanently impair the normal maturation of cerebral rhythms, the net result being that adults with congenital cyanotic heart disease, even if operated on, may still show E.E.G. patterns of juvenile type.

From these studies it would appear that either postoperative changes in the retinal vasculature are not paralleled by similar

changes in the cerebral blood vessels, or that if changes in the cerebral vasculature do occur they are not followed by an improvement in the E.E.G., persistent abnormalities of which reflect other irreversible disturbances.

Summary

Retinal vascular changes are present in all cases of congenital cyanotic heart disease. The severity of these changes is most marked in patients with the highest P.C.V.s.

The E.E.G. is frequently abnormal in congenital cyanotic heart disease even in the absence of overt neurological symptoms and signs. The degree of E.E.G. abnormality bears no relation to the P.C.V.

The dramatic reversion towards normality shown in the retinal vessels after correction of the cardiac lesion is not paralleled by improvements in the E.E.G. In only a minority of cases is an improvement in the E.E.G. detectable three months after operative correction of the cardiac defect.

The E.E.G. defect in congenital cyanotic heart disease is not a simple functional disturbance directly related to arterial desaturation or to a diminution of cerebral blood flow from polycythaemia.

We would like to thank Professor J. F. Goodwin, Professor H. H. Bentall, and Dr. C. Oakley for allowing us to study patients under their care, and Dr. C. Dollery for helpful criticism.

E. M. K. was supported by the Tobacco Research Council and the photographic material was supplied by the Medical Research Council.

Catabolism of Serum γ G-globulins in a Cancer Patient and a Normal Volunteer

D. E. H. TEE,* M.B., B.S., M.C.PATH.; J. WATKINS,* B.SC., PH.D.

Brit. med. J., 1967, 4, 210-212

It has been shown that the half-life of serum γ G-globulins is apparently characteristic of the species of origin (Spiegelberg and Weigle, 1965). However, it is also well established that the half-life value may be influenced by several factors, in particular by its dependence on the concentration of γ G-globulin in the serum (Fahey and Robinson, 1963; Fahey and Sell, 1965).

Several workers have studied the catabolism of electrophoretically and antigenically distinct components of the γ G-globulin of mice (Fahey and Sell, 1965; Tee, Watkins, and Wang, 1965). Each of these components was found to have a different half-life in the normal mouse. In view of the heterogeneity in biological functions of the antibodies associated with these components and the possible implications for immuno-

logical tumour enhancement (reviewed by Bloch, 1965), it is surprising that little significance appears to have been attached to the findings of those workers (Mills, Calkins, and Cohen, 1961) whose experiments indicate a similar catabolic heterogeneity of γ G-globulins in man.

This paper reports some preliminary results of studies being made in this laboratory of the catabolic heterogeneity of human γ G-globulins.

Volunteers and Methods

Two male volunteers were used in this study. The control subject was one of us (J.W.) aged 31. The other volunteer was a patient aged 43, who over the previous seven years had undergone surgery for the removal of six distinct primary carcinomas. In 1960 he had a laryngectomy for carcinoma of

*Department of Pathology, King's College Hospital Medical School, London S.E.5.

the larynx; in 1962 a total colectomy for four distinct primary carcinomas of the caecum, transverse colon, descending colon, and rectosigmoid junction respectively; and in 1965 a pancreaticoduodenectomy for an adenocarcinoma of the duodenum. In addition, since 1960 he has had excised a number of hamartomata arising from sebaceous glands of the face. More complete details of this patient have been presented as a case report (Muir, Yates-Bell, and Barlow, 1967). There is no clinical or histological evidence of any of these primary neoplasms metastasizing to lymph nodes or distant organs. Indeed, it might be suggested that he possesses some immunological mechanism that prevents the development of metastases.

Two sources of serum γ G-globulins were used in this experiment. The first was pooled normal plasma obtained from a blood bank. The second was serum obtained from the patient. γ G-globulins were isolated from these plasma and serum samples by chromatography on diethylaminoethanol cellulose columns.

Starch-gel electrophoresis of these protein preparations showed the characteristic broad zone associated with γ G-globulins and the complete absence of other serum proteins. Under sedimentation velocity conditions in the analytical ultracentrifuge the preparations gave a single symmetrical schlieren peak, sedimenting with the velocity of 7S proteins. There was no evidence of the presence of dimer. These γ G-globulin preparations reacted with anti-human γ G-globulin antiserum and not with either anti-human γ A-globulin or γ M-globulin antiserum.

The normal γ G-globulin from the plasma pool was labelled (McFarlane, 1958) with iodine-131 and the γ G-globulin from the patient was labelled with iodine-125. The labelled proteins had a specific radioactivity of about 20 μ Ci/mg. protein. The two radioactive preparations were mixed and diluted with pooled plasma to produce a solution containing approximately 25 μ Ci of iodine-131 and 25 μ Ci of iodine-125 per ml. Each iodine isotope in the mixture has a characteristic radiation energy and can be measured quantitatively in the presence of the other.

Aliquots (2 ml.) of this solution were injected into the ante-cubital vein of each volunteer. The volunteers received sodium iodide (40 mg./day) for a week before injection of the radioactive dose and subsequently throughout the period of the experiment.

Residual radioactivity in each of the volunteers was measured over a period of nine weeks by means of scintillation counting of serum samples and by whole-body radiation counts.

The radiation counts so obtained were corrected for isotope decay. Biological half-life values were calculated in the usual manner from plots of the logarithm of the corrected count against time.

Observations

The relation between residual activity and time could not be satisfactorily represented as linear in either of the volunteers. The lines joining the experimental points took the form of shallow curves showing increasing positive divergence from linearity with time. For practical purposes the curves could be thought to be made up of two intersecting straight lines, fitting very closely the experimental points measured over the periods 7 to 28 days and 28 to 63 days respectively. The half-life values obtained from serum counting are summarized in Fig. 1.

Geiger-Müller probes were used for whole-body radiation counting. Since the emission energies of iodine-125 are too low to be detected by this method, it was only possible to measure iodine-131-labelled protein. However, the half-life values obtained for "normal" γ G-globulin by means of whole-body counting were in excellent agreement with those obtained from serum counting.

The γ G-globulins were broken down at different rates in the two volunteers. γ G-globulins in the patient were broken down at a faster rate than those in the control subject. The original source of the labelled proteins appears to have no effect on the observed breakdown rate.

Fig. 1.—Half-life values of γ G-globulins. □ γ G-globulins from normal plasma. ■ γ G-globulin isolated from serum of patient with cancer.

The breakdown rates showed some degree of time dependence, since half-life values measured over the period 28 to 63 days are higher than those measured over 7 to 28 days. A more satisfactory demonstration of the time dependence of the half-life was provided by quantitative starch-gel electrophoresis of γ G-globulins in serum samples taken at various times (Tee *et al.*, 1965).

Under the starch-gel electrophoresis conditions we employ in this laboratory (discontinuous borate-glycine buffer system pH 8.6; 4 hour; 8–10 v. cm.⁻¹) the γ G-globulin preparations from normal serum contain approximately equal amounts of proteins migrating towards the anode (γ_1 fraction) and towards the cathode (γ_2 fraction), as measured by the radioactive label.

The radioactivity ratio γ_2/γ_1 was calculated for each serum sample and the logarithm of this ratio plotted against time (Fig. 2). It can be seen that the ratio is not constant, as would be the case if both γ_2 and γ_1 fractions were broken down at identical rates. Instead the γ_2 fraction is being broken down at a considerably faster rate than the γ_1 fraction.

Discussion

Though most workers (reviewed by Schultze and Heremans, 1966) have thought pure γ G-globulin to be degraded at a homogeneous catabolic rate, most of these workers have measured the half-life over a period of only a few weeks. It would be practically impossible to demonstrate heterogeneity of catabolism over short periods of time in terms of changes in rate of disappearance of radioactive protein.

Fig. 2.—Relative survival of the serum γ_1 and γ_2 fractions in man.

The experiments reported in this paper, conducted over a period of nine weeks, indicate that different electrophoretic fractions of γ G-globulin possess different breakdown rates; the observed half-life of the entire γ G-globulin preparation being a mean of the individual values. The overall breakdown rate is non-linear and the half-life values increase with time. However, mean half-life values measured over the nine-week period were 25 days (J. W.) and 18 days (patient) respectively. These half-life values are in good agreement with those of Cohen and Freeman (1960), who reported half-life values of 21–26 days for γ G-globulins in the normal individual.

The half-life values obtained from the present experiment appeared to be characteristic of the catabolism of the individual and to be independent of the source of the labelled γ G-globulin.

The difference in the half-life values found for γ G-globulins in J. W. and the patient cannot be attributed to concentration dependence of γ G-globulin catabolism, since it was found that their serum γ G-globulin levels were 838 and 940 mg./100 ml. respectively. However, starch-gel electrophoresis experiments showed that in the patient the serum γ_2/γ_1 ratio was approximately 2:1, as compared with 1:1 in J. W. The 2:1 γ -globulin ratio would be expected to predispose the overall γ G-globulin catabolic rate in the cancer patient to be faster than that in the control subject with a 1:1 ratio, since it has been shown (Fig. 2) that the γ_2 fraction is broken down faster than the γ_1 fraction.

The possibility that the catabolic rates are affected by allo-zytic differences between the donor γ G-globulins and those of the recipient cannot be overlooked. The patient had had several transfusions during the course of operations for removal of his neoplasms. However, J. W. carried out a similar experiment to that reported in this paper on himself a year previously using homologous γ G-globulin from a normal individual. Two γ G-globulin preparations were used for this particular experiment. One was obtained from the normal donor directly and labelled with ^{125}I , the other was obtained from this donor after a "booster" injection of tetanus toxoid and labelled with ^{131}I . Both labelled γ G-globulin preparations showed the same heterogeneous breakdown pattern over a period of 15 weeks. The apparent biological half-life values were identical to those reported for J. W. in this paper. The results of this experiment

(Watkins and Tee, 1966), together with the present observations, indicate that the observed catabolic phenomena are not artifacts produced by immune response to the injected homologous γ G-globulin.

This work is now being extended to study the catabolism of γ G-globulins in other subjects, including both normal volunteers and patients with various pathological conditions.

Summary

The survival of radioiodine-labelled serum γ G-globulins was determined in a normal volunteer and in a cancer patient over a period of nine weeks.

It was found that different electrophoretic fractions of the γ G-globulin broke down at different rates. This catabolic heterogeneity of the γ G-globulins gave rise to an apparent time dependence of the observed half-life value. Mean half-life values, as measured over the entire nine-week period, were 25 days for γ G-globulins in the normal volunteer and 18 days for the same γ G-globulin preparation in the cancer patient. The breakdown rates in both individuals appeared to be independent of the source of the labelled γ G-globulins.

We thank Mr. E. G. Muir, Dr. S. B. Osborn, and Mr. M. B. Clark, of King's College Hospital, for their help and interest; and Mr. B. Godfrey, of the Radiological Protection Service, for some of the measurements of total body radiation. This work was carried out with the aid of a grant from the British Empire Cancer Campaign for Research.

Preliminary Communications

Demonstration of an Enzyme Variant in a Case of Congenital Methaemoglobinaemia

Brit. med. J., 1967, **4**, 212–214

In normal individuals methaemoglobin in the red cell is maintained at a very low level (<1%). Raised levels may be due to: (a) intake of certain drugs which overcome the normal mechanism for maintaining a high reduction potential in the cell—removal of the toxic influence results in disappearance of methaemoglobin; (b) presence of an abnormal haemoglobin which is more susceptible to oxidation as well as being more resistant to reduction in the cell; and (c) deficiency of reduced nicotinamide adenine dinucleotide coupled methaemoglobin reductase.

Numerous cases of congenital methaemoglobinaemia due to deficiency of the reduced nicotinamide adenine dinucleotide coupled "diaphorase" have been described, the affected individual showing very low enzyme activity in both haemolysates and red cells, while the parents show intermediate levels of

activity (for review, see Jaffé and Heller, 1964). However, it has not been clear whether the defect was one of enzyme synthesis or of enzyme structure.

In the case of congenital methaemoglobinaemia here reported, it is shown by starch-gel electrophoresis of a partially purified red cell extract that the propositus possesses an electrophoretically distinct enzyme, indicating that the defect lies in the synthesis of a structurally altered enzyme protein. Normal individuals appear to possess at least two isoenzymes.

CASE REPORT

The patient, a boy aged 9, had a history of frequent upper respiratory infections and of becoming blue since birth. His milestones of development were slightly delayed, and he was not progressing well at school.

On clinical examination his lips were slightly greyish blue and his complexion was rather dusky; this finding suggested the possibility of methaemoglobinaemia as a diagnosis. There were no other abnormal physical signs. Investigations confirmed the presence of methaemoglobin in his blood, and this was again found on

numerous occasions. Chest x-ray films, routine urine analysis, and urinary chromatography for amino-acids were all normal. The tuberculin test and the Wassermann reaction were negative.

An educational psychologist, using the Wechsler Intelligence Scale, assessed the patient's full-scale I.Q. as 105 (verbal I.Q. 101, performance I.Q. 108), and noted that his "functioning fluctuates between near subnormal and very superior." Since that time, though slow and lacking in concentration, he has made reasonable progress with the aid of a remedial teacher.

Treatment with large doses of oral ascorbic acid had no obvious effect on the slight cyanosis, though his mother stated that he was better for it.

Family History.—Mother and two siblings are alive and well. There is a history of diabetes on the maternal side, and a cousin has suffered from acute haemolytic anaemia associated with glandular fever.

Investigations.—Haemoglobin 13.6 g./100 ml.; P.C.V. 40%; red cell count 4,700,000/cu. mm.; reticulocytes <1%; M.C.H.C. 34 g./100 ml.; M.C.H. 28 μ g.; M.C.V. 85 cu. μ . The red cells appeared normal on the stained blood film. Serum iron 97 μ g./100 ml. Haptoglobins (type 2-2) present in plasma. The methaemoglobin present amounted to 4.4% of the total haemoglobin. Starch-gel electrophoresis of haemoglobin showed no abnormal haemoglobin; Hb-A₂ was within normal limits. The methaemoglobin A present migrated in the normal position for methaemoglobin A. Spectroscopic examination showed that the α -absorption band was between 630 and 635 m μ . The starch-gel electrophoretic and spectroscopic properties of the methaemoglobin indicated that it was normal haemoglobin and not a type of haemoglobin M.

PREPARATION OF ENZYME EXTRACT FROM PATIENT'S RED CELLS

The separation of haemoglobin from other red cell proteins was carried out with diethylaminoethyl (D.E.A.E.) cellulose by means of a batch technique adapted from the methods of Hennessey *et al.* (1962) and Stansell and Deutsch (1965). Heparinized venous blood was centrifuged, plasma and buffy coat were removed, and the packed cells were washed three times with 0.9 g. of sodium chloride per 100 ml. Five millilitres of packed red cells were haemolysed in four volumes of ice-cold 0.005M tris (tris-(hydroxymethyl)-aminomethane) brought to pH 7 with phosphoric acid and centrifuged for 30 minutes at 35,000 g at 0° C. to remove stroma.

The decanted supernatant was passed through a Sephadex G-25 column (3 by 18 cm.), pre-equilibrated with the 0.005M tris-phosphate buffer, pH 7. The equilibrated haemolysate was collected direct into approximately 60 g. of D.E.A.E. cellulose (Whatman DE-52) equilibrated with the same buffer.

The haemolysate-cellulose suspension was stirred gently in the cold for three hours, then filtered under vacuum and washed with 0.005M trisphosphate, pH 7, until the washings were clear. This removed most of the haemoglobin and left the enzyme protein on the cellulose. The cellulose was then resuspended in the same buffer and packed under gravity into a column, 1.5 by 60 cm. The enzyme fraction was eluted from the column with 1M sodium chloride brought to pH 5.6 with phosphoric acid. This process concentrated the non-haemoglobin proteins to about 30 ml., and these were further concentrated to about 0.5 ml. by vacuum dialysis against the tris-borate-E.D.T.A. buffer, pH 8.6, used for electrophoresis. This concentrated extract had about 10 times the enzyme activity of packed red cells and was used for electrophoresis. The extract also contained a number of other red cell enzymes and proteins as well as a small amount of haemoglobin.

ELECTROPHORESIS AND STAINING OF THE GEL

Electrophoresis was carried out on starch gels with tris-borate-E.D.T.A. buffer, pH 8.6 (see Huehns and Shooter, 1965). A current of 30 mA was passed for four hours.

The enzyme has about 9,000 times the activity with the dye 2:6-dichlorophenolindophenol as substrate than it has with methaemoglobin (Scott and McGraw, 1962). The property of reducing this dye in the presence of reduced nicotinamide adenine dinucleotide was therefore used in locating the different bands of enzyme activity on the gel. Chromatography paper (Whatman 3 MM) was dipped into a concentrated filtered solution of 2:6-dichlorophenolindophenol containing about 50 mg. of reduced

nicotinamide adenine dinucleotide per 100 ml. of 1M tris buffer, pH 7.5, with 0.3 mM E.D.T.A. The saturated paper was placed on the cut surface of the gel and the whole covered with a fine polyethylene sheet to exclude air. When sufficient dye had diffused into the gel to give a uniformly blue background the paper was removed and the polyethylene replaced. The diaphorase activity could be seen on the gel as decolorized bands after approximately 15 minutes at room temperature. Photographs were taken with transmitted light on microfilm (Kodak type 5453) with a deep yellow filter.

ASSAYS OF METHAEMOGLOBIN REDUCTASE

In whole cells the method of Jaffé (1959) was used, with adenosine as "nutrient" substrate. Methaemoglobin was estimated, utilizing the difference in spectral absorption of the met- and carbonmonoxy-derivatives of haemoglobin at 632 m μ . This method is capable of measuring as little as 0.5% of the oxidized pigment. For haemolysates the enzyme was estimated as described by Scott (1960).

RESULTS

Whole Cells.—The results are shown in Fig. 1. The patient's cells show a very low rate of reduction of methaemoglobin compared with those of the mother and normal controls, which had almost completely re-formed oxyhaemoglobin after 17 hours. The mother falls within the range for normal individuals. In the absence of nutrient substrate there was a rise in the methaemoglobin level in the first three hours of incubation of about 10%, after which time the levels remained constant.

Fig. 1.—Reduction of methaemoglobin to haemoglobin during incubation of nitrite-treated red cells. The reduction of methaemoglobin is expressed as a percentage of the methaemoglobin content of the nitrited washed cells at the start of the incubation. ○—○ Patient with methaemoglobin reductase deficiency. △—△ Mother of patient. ●—● Normal controls.

Haemolysates.—The results are shown in the Table. The propositus again shows very low activity while the mother falls within the normal range.

Methaemoglobin Reductase Activity in Haemolysates

	Change in optical density at 600 m μ /1 ml. packed red cells per minute
Patient	0.15
Mother	0.95
Normal controls (25)	1.37 $\pm$ 0.40 (S.D.)

Starch-Gel Electrophoresis.—In normal individuals at pH 8.6 two light bands appear migrating more slowly than Hb A towards the anode (Fig. 2). The patient has only one band of intermediate mobility and much lower activity as judged by the rate and intensity of decolorization of the dye. The patient's mother shows the two normal bands, as well as a weak band in the same position as

that of her son. This is not shown in the photograph, as the relative intensities of the bands made this technically difficult. No such band has been seen in 35 unrelated normal individuals studied in this way, and dilution of the normal concentrate did not alter the electrophoretic pattern.

FIG. 2.—Starch-gel electrophoresis of enzyme extract prepared from red cells stained for reduced nicotinamide adenine dinucleotide-methaemoglobin reductase. (i) normal red cells, (ii) methaemoglobinaemic red cells, (iii) normal red cells.

DISCUSSION

The deficiency of "coenzyme factor I" (diaphorase, reduced nicotinamide adenine dinucleotide linked methaemoglobin oxidoreductase) described by Gibson (1948) has been confirmed in many patients with congenital methaemoglobinaemia.

The deficiency could be the result of two possible situations: (a) reduced rate of synthesis of a normal enzyme; and (b) normal rate of synthesis of an abnormal enzyme which is either stable, with a low specific activity, or unstable, resulting in non-uniform distribution of activity in old and young cells.

Scott (1962) and Scott *et al.* (1965) have partially purified reduced nicotinamide adenine dinucleotide methaemoglobin reductase from methaemoglobinaemic red cells. This enzyme shows altered properties with respect to pH and temperature stability compared with enzyme from normal individuals. Keitt *et al.* (1966) found that old red cells separated by ultracentrifugation from patients with this enzyme deficiency contained more methaemoglobin than young cells. These results suggest that in these patients the enzyme activity in the red cells is due to the presence of an abnormal unstable enzyme. The present finding of an electrophoretically abnormal enzyme is consistent with this idea. However, the defect present in this family may be different from that found by other investigators, because the amount of methaemoglobin in the patient was only 4.4% of total haemoglobin, whereas in other reported cases values range between 8 and 45% (Jaffé and Heller, 1964; Fialkow *et al.*, 1965; Jaffé *et al.*, 1966). Furthermore, the mother of our patient has an enzyme activity which falls within the normal range, whereas the heterozygotes reported by Scott (1960) have approximately half the normal enzyme levels. The finding of normal enzyme levels in the mother of our patient is consistent with the presence of both normal and abnormal enzymes. The presence of the abnormal enzyme protein in the mother allows the definite identification of the heterozygous state, which previously has only been presumptive, being based on the level of enzyme activity present. The father of our patient has so far not been studied.

The association of the synthesis of abnormal proteins or enzymes with disease has been well documented in, for example, the haemoglobinopathies (see Huehns and Shooter, 1965) and

in glucose-6-phosphate dehydrogenase deficiency (Marks, 1964). The present investigation suggests that congenital methaemoglobinaemia due to reduced nicotinamide adenine dinucleotide methaemoglobin reductase deficiency is also of this type, and study of other patients with this disease may show that it can also be caused by a number of electrophoretically distinct enzymes.

SUMMARY

A partially purified protein extract was prepared from the red cells of a patient with congenital methaemoglobinaemia and from normal individuals. Electrophoresis of these extracts at pH 8.6 and staining with a 2:6-dichlorophenolindophenol/reduced nicotinamide adenine dinucleotide system showed two decolorized bands of diaphorase activity in normal individuals and a single band of intermediate mobility in the patient. The mother of the patient showed both normal and abnormal enzymes. It is suggested that the enzyme deficiency in this patient is the result of the synthesis of an abnormal form of reduced nicotinamide adenine dinucleotide linked methaemoglobin reductase.

We wish to thank Dr. G. A. Matthews, consultant pathologist, West Herts Hospital, for his co-operation in undertaking many of the laboratory investigations, and Dr. H. M. Brunt for having kindly referred this patient.

Medical Memoranda

Severe Anaphylactic Reaction after a Soap Enema

Brit. med. J., 1967, 4, 215

While local reactions and skin eruptions have been described following the use of soap enemas (Barker, 1945; Bendit, 1945; Turrell, 1959) there appears to be no record of an anaphylactic reaction of the type and severity shown in the following case.

CASE REPORT

The patient, a 33-year-old para-1, was booked for domiciliary confinement. Her past obstetric career had been uncomplicated and her previous health good. In particular, she had no history of asthma, skin rashes, or other allergic phenomena, and there was no such family history. Three days before her expected date of delivery she experienced vague abdominal pains, but labour failed to become established. The district midwife administered an enema, using a solution of "two handfuls" of a proprietary brand of soap-flakes in approximately 2 pints (1,140 ml.) of warm water and instilled by means of a tube and funnel. Immediately this solution was run in the patient noted that her mouth was becoming swollen, and that she had "pins-and-needles" in her limbs and tightness in her chest. She was unable to swallow and felt as if she was choking. On attempting to rise she collapsed and became unconscious, and when medical aid arrived shortly afterwards the pulse and blood pressure could not be recorded and the foetal heart was 40 beats a minute. Oxygen therapy was begun and she was brought to the near-by hospital without delay.

On admission she was pale and acutely shocked, but was conscious and able to answer simple questions. The blood pressure was 70/40 mm. Hg. The radial pulse was barely palpable and the apical heart rate 88 a minute. There was a spreading urticaria on the thighs, upper arms, trunk, and face which became more pronounced during examination. On auscultation of the chest there was generalized bronchospasm. The foetal heart rate was 160. Treatment was instituted promptly with 0.5 ml. of 1:1,000 adrenaline in 5 ml. of sterile saline subcutaneously and 100 mg. of hydrocortisone and 10 mg. of Piriton (chlorpheniramine maleate) intravenously. Oxygen therapy was continued. Within two hours her blood pressure had risen to 110/90, the rash was beginning to fade, and regular labour contractions had begun. Labour progressed rapidly and after a further two hours, when the cervix was almost fully dilated, the membranes ruptured and there was thick meconium staining of the liquor. The foetal heart rate dropped to 80. Mid-cavity forceps delivery was effected without difficulty.

The baby, a male weighing 5 lb. 8 oz. (2.5 kg.), had inspired meconium and had an Apgar score of only 4, but after clearing of the airways, endotracheal intubation, and oxygen administration his condition improved and spontaneous respiration was established after 15 minutes. The third stage of labour was completed normally within 10 minutes. The puerperium was normal. Bowel function returned on the second day and continued normally. The infant progressed well and his condition was satisfactory on dismissal.

COMMENT

Many substances have been employed in clearing enemas—olive oil, paraffin, glycerin, turpentine, and soap, to name but a few. The commonest of these is undoubtedly soap, which varies widely in chemical composition and may contain such irritating substances as strong alkali, phenol, and potash. Turrell (1959) described the irritating effects of hypertonic phosphate on the colonic mucosa. Lewis (1965) condemned the use of strong sodium biphosphate solution for enemas and

quoted instances where different kinds of hospital soap were collected together in a jar and diluted quite arbitrarily with 200–2,000 ml. of water. One of his cases (settled out of court) had received an enema with scouring powder. As reported by Lewis (1965), Shambotte and Degrotte in 1960 recorded a fatal case of renal anuria where an 8-day-old baby received an enema containing a phenol soap.

Local reactions have varied from simple irritation to frank necrosis. According to Gabriel (1937) these are more common than is generally supposed, and Hicks (1944) found that one-third of his series had suffered irritative effects. Bendit (1945) described a case of rectal gangrene in a patient who received two successive soap enemas, and a case of severe haemorrhage is reported from Minneapolis (Lewis, 1965) following the use of undiluted soap. Turrell (1959) stated that where there is local reaction, proper evaluation of the colonic mucosa at sigmoidoscopy may be interfered with, and not only may a barium enema be much more uncomfortable, but x-ray appearances may be misleading owing to loss of haustrations.

In most of the cases quoted recovery occurred, but abnormal bowel function persisted for three months or more (Lewis, 1965), and Pinnock (1937), Murray (1937), and Gabriel (1937) quote six deaths from soapsuds enemas. While specific series are lacking, standard works of dermatology quote erythematous, papular, or scarlatiniform rashes as "occasional complications" of enemas and mention the danger of stirring up an anal eczema, which may become more generalized and may follow the use of water alone.

Enemas are sometimes used in hospital and domiciliary practice and occasionally by patients themselves without a valid indication. They are usually effective, but often oral preparations or suppositories might have been equally so. Many of the substances used may be harmful. Phenol-containing soaps are absolutely contraindicated and proprietary soap powders or flakes may be highly dangerous. It appears that insufficient attention has been paid to the chemical composition of the soap and the strength of the solution. The recommended dose of soft soap is one teaspoonful diluted in a quart (1,140 ml.) of warm water. Where serious reactions occurred preparations other than soft soap were used and the solution was often very much more concentrated. Repeated soap enemas may cause mucosal damage, particularly if a portion of the first enema is retained. Introduction of the enema fluid under high pressure is hazardous as the haemorrhoidal venous plexus may be entered, bypassing the portal circulation and liver detoxification. There is also the risk of bowel perforation where local infection pre-exists. Finally, it is suggested that enemas may be contraindicated where there is a history of allergic phenomena or sensitivity reactions, particularly to soap derivatives.

I wish to record my thanks for helpful advice and literature to Mr. M. R. Neely, consultant obstetrician, Ulster Hospital, Dundonald, Belfast, under whose supervision this patient was treated.

DONALD SMITH, M.B., CH.B., M.R.C.O.G.,
Senior Registrar, Royal Maternity Hospital, Belfast.

Fatal Lactic Acidosis after an Overdose of Phenformin

Brit. med. J., 1967, 4, 216

A number of papers have been published concerning the dangers encountered in the use of the diguanide phenformin as an oral hypoglycaemic agent (Walker *et al.*, 1960; Ewy *et al.*, 1963; Tranquada *et al.*, 1963). The purpose of this report is to record the fatal outcome in a patient who had ingested 50 mg. of phenformin in excess of the prescribed dose.

CASE REPORT

The patient, a 64-year-old housewife, had been known to suffer from maturity-onset diabetes for four years. She was treated with chlorpropamide for 18 months, and then with a 1,000-calorie diet (130 g. of carbohydrate) alone for three months. She remained more than a stone (6.4 kg.) above the standard weight for her height and was therefore started on phenformin in May 1964 in order to treat her mild hyperglycaemia and to facilitate weight reduction. The dose of phenformin was gradually increased and for five months before admission to hospital, on 10 June 1965, she was taking 25 mg. q.i.d. She had been in good health until 24 hours before admission, when the sudden onset of generalized abdominal pain was closely followed by vomiting of watery material. Her bowels were regular and a normal motion was passed in the interval between the onset of symptoms and admission. She denied any dyspeptic history or symptoms referable to the renal tract or cardiovascular system. The pain remained generalized and did not radiate from the abdomen. Twelve hours before the onset of her symptoms (36 hours before admission) she had mistakenly ingested two 25-mg. phenformin tablets in excess of her normal dose—that is, a total of 50 mg. in divided dosage in 12 hours.

On examination the patient, who lived in comfortable circumstances, was ill, pale, and obese and had acidotic respirations, but acetone could not be detected in the breath. She was moderately dehydrated. The rectal temperature was 88.2° F. (31.2° C.), she was orientated and examination of the peripheral nervous system showed no abnormality, though the plantar responses could not be elicited. Neither pupil reacted to light or to accommodation, and the left was larger than the right. The left fundus was normal and the right was obscured by cataract. Her chest was clinically and radiologically normal, and examination of the abdomen (including rectal investigation) showed no abnormality. The pulse was of poor volume, though regular at 100 per minute. No signs of cardiac failure were observed and the heart sounds were normal. Blood pressure was recordable at 96/60 mm. Hg only after 7 mg. of metaraminol (Aramine) had been given intravenously.

The laboratory findings on admission were as follows: Hb 16.6 g./100 ml.; W.B.C. 20,600/cu. mm., differential normal; E.S.R. 11 mm. in the first hour. Urinalysis showed moderate proteinuria, no glycosuria, and only a trace of ketones to Acetest and negative ferric chloride reaction. There were no cells or casts in the urinary deposit. E.C.G. showed left ventricular hypertrophy and ischaemia; J waves were not present. Serum and electrolyte values (sodium, potassium, and chloride) were normal. Blood urea was 140 mg./100 ml., falling to 84 mg./100 ml. after dehydration. No salicylates were detected in the serum, and the values of serum transaminases (S.G.O.T., S.G.P.T.) and of serum amylase were normal. The plasma CO₂ combining power was 1.8 mEq/l. Blood sugar was 140 mg./100 ml. and the serum lactic acid level was 240 mg./100 ml. (26.7 mM./l.) five hours after admission.

Therapy was started with intravenous dextrose 5% and isotonic saline with added metaraminol and sodium bicarbonate. After 12 hours of such treatment her condition remained desperate. Despite giving 400 mEq of sodium bicarbonate and 120 mg. of metaraminol a total of 2,700 ml. of intravenous fluid she remained oliguric and grossly acidotic. At this point, 12 hours after starting treatment, the CO₂ combining power was 4.9 mEq/l. and the arterial pCO₂ 6.92 (Pco₂ less than 30 mm. and standard bicarbonates less

than 6 mEq/l.). The rectal temperature had risen to 94° F. (34.5° C.).

The patient's condition and blood pressure improved slightly after the infusion of 540 ml. of 10% dextrose in two hours, and 600 ml. of urine was passed in the second 12 hours, the blood pressure being 90 to 110/50 to 60 mm. Hg. Twenty-eight hours after admission she had a cardiac arrest. Immediate resuscitation was unsuccessful. Post-mortem examination failed to reveal any significant disease apart from thrombosed splenic vein.

Comment.—The only recognized factor which could contribute to the metabolic acidosis was the history of taking 50 mg. in excess of her usual 100 mg. daily of phenformin. She had no significant uraemia, salicylism, infection, or external cause for her acidosis and there was no preceding period of severe carbohydrate deprivation.

DISCUSSION

Walker *et al.* (1960) discussed the action and side-effects of phenformin. It was suggested that associated acidosis was more likely to occur in juvenile diabetics on phenformin than in older diabetics. The degree of lactic acidosis found in our patient is an example of a rare occurrence in such an elderly mild diabetic. Dobson (1965) reported a case of attempted suicide by means of phenformin. A dose of 850 mg. was ingested but no acidosis was present. It was suggested that the gastrointestinal irritation may protect against the absorption of an overdose of this drug. This was not the position with our patient.

Huckabee (1961) described an ill-defined group of patients, not necessarily diabetic and not having any drug in common, who died in severe metabolic acidosis caused mainly by raised serum lactic acid. He believed the common factor in such cases was widespread tissue hypoxia of indeterminate cause. Such a vague description could of course fit our patient, irrespective of any drugs, but the distinct possibility exists that the trigger mechanism for the development of lactic acidosis was the modest overdose of phenformin. It is known that blood lactic acid levels may be expected to rise under the influence of phenformin in doses similar to those taken by our patient, but normally the rise is modest—for example, 4 to 31 mg./100 ml. (Craig *et al.*, 1960). The finding of 240 mg./100 ml. in our patient is clearly of a different order of magnitude and difficult to explain. There was no clinical or post-mortem evidence of any process to cause hypoxia, which is a well-recognized cause of hyperlactacidaemia (Shepardson *et al.*, 1962).

We gratefully thank Mr. T. Clark (City Analyst) and Professor S. C. Frazer and their staffs for the biochemical estimations so willingly carried out.

New X Wave in Electrocardiographic Complex

Brit. med. J., 1967, 4, 217

Changes in the electric potentials during a cardiac cycle producing positive or negative deflections in an electrocardiographic tracing have been designated by the well-known PQRSTU (including R' or r' and S' or s'). All these waves can be individually recognized in most of the leads. An additional upright deflection after U is described below which so far as we are aware has not been reported in English literature. This was encountered during routine electrocardiographic recordings of cases of cerebrovascular accidents.

CASE REPORT

The patient, a 55-year-old Hindu man, was admitted to hospital on 16 February 1966 with a history of sudden loss of consciousness lasting about half an hour and inability to use the right upper and lower limbs two hours before admission.

On examination he was found to be of average build. He was conscious, but had expressive aphasia. Pulse was 56 per minute,

FIG. 1.—Electrocardiographic record taken on 18 February 1966, showing an additional upright wave marked X in L2, L3, aVF, V1, V2, and V3.

B.P. 160/98 mm. Hg. There was right hemiplegia with exaggeration of deep tendon reflexes. Right plantar response was extensor. Fundus showed arteriosclerotic changes. Cerebrospinal fluid and routine blood and urine examinations were normal. Venereal disease research laboratory test was negative in blood. He remained more or less in the same state until 28 February, when he suddenly lost consciousness and died an hour and a half later. Necropsy was refused.

Electrocardiograms were taken on 16, 18, 20, 26, and 28 February. The first immediately on admission and the last a few minutes before death.

Electrocardiographic Findings.—Analysis of the record of 18 February (Fig. 1), two days after admission, shows a heart rate of 50 per minute, P-R interval 0.12 sec., and Q-Tc 0.46 sec. Configurations of PQRST can be recognized in all the leads. The U wave is distinctly identifiable in nearly all the leads. An extra upright deflection (termed X) following U and just preceding P of the second cycle is seen in L2, L3, aVF, V1, V2, and V3. It is most prominent in lead aVF (Fig. 2), where it measures a little more than 0.5 mm. in height and 0.2 sec. in duration.

FIG. 2.—Prominent X in lead aVF.

This additional wave was not seen in any of the electrocardiograms (Fig. 3) recorded on four other occasions during his stay in hospital.

FIG. 3.—Normal tracings without any extra deflection. Only leads aVF shown. A, 16 February. B, 20 February. C, 26 February. D, 28 February.

COMMENT

Our first impression was to reject this extra deflection as an artifact due to stylus or other mechanical defect. But the isoelectric line was steady and unwavering and all the neighbouring waves—T, U, and P—were prominent and unmistakably clear. This extra deflection could also be made out in a number of leads at the same time sequence. On this basis identity of this extra upright deflection as a separate wave could not be doubted.

We venture to suggest that, like the U wave, the X wave may also indicate a very delayed completion of the process of repolarization. Readjustment of potassium and sodium ions through the cell membrane may not have been stabilized by the end of the U wave.

Current Practice

DISEASE OF THE DIGESTIVE SYSTEM

Hiatus Hernia

MICHAEL ATKINSON,* M.D., F.R.C.P.

Gastro-oesophageal reflux is one of the commonest causes of dyspepsia in this country and is usually due to hiatus hernia. Yet many clinicians still in the prime of their careers were trained before the syndrome of gastro-oesophageal reflux or the significance of hiatus hernia was generally appreciated, and 20 years ago these received little attention in the medical curriculum. It is hardly surprising that today hiatus hernia is often overlooked, and it is worth restating the ways in which it may present.

Types of Hernia

On anatomical grounds hiatus hernia is commonly divided into three types.

The *sliding type* is most frequently encountered, and here the oesophago-gastric junction moves up through the hiatus into the chest producing a bell- or funnel-shaped configuration. These hernias present with symptoms of gastro-oesophageal reflux, and though they are often quite small and reducible the severity of symptoms bears no relation to their size or mobility. Only when oesophagitis has caused much fibrosis is the oesophagus shortened, and hence "short oesophagus" is virtually always the consequence and not the cause of the hernia.

The *para-oesophageal* variety is characterized by herniation of the fundus of the stomach and gastro-colic omentum through the hiatus alongside the cardia, which retains its normal position. This is the least common variety and often produces few symptoms. It may be impossible to distinguish from herniation through a diaphragmatic defect separate from but close to the oesophageal hiatus—which is not of course a true hiatus hernia yet is believed by many to be the usual origin of this type of hernia.

The *mixed* variety is far commoner than a true para-oesophageal hiatus hernia, with which it is often confused because of difficulty in determining the positions of the cardia relative to the hiatus. Here the symptoms are usually those of gastro-oesophageal reflux, though many remain silent. Symptoms of obstruction may occur, since the cardia lies above the diaphragmatic hiatus—the herniated portion of the stomach may become distended with food if the hiatus is small.

Causation of Hiatus Hernia

Hiatus hernia is usually an acquired condition, the causes of which are still incompletely understood. Unlike other abdominal hernias it is seldom clearly related to trauma or to sudden muscular straining increasing intra-abdominal pressure. Very occasionally a patient does feel a sharp tearing retrosternal pain on straining shortly before symptoms of gastro-oesophageal reflux commence, but it seems probable that this is a separate entity from the common type of hiatus hernia, and it usually occurs in younger subjects.

*Consultant Physician, Worcester Royal Infirmary.

At one time congenital laxity of the diaphragmatic hiatus was believed to be the basic abnormality causing hiatus hernia. However, hernia is not common after diaphragmatic paralysis, when the hiatus might be expected to be lax, which casts doubt upon this view. Perhaps of greater causative importance is impairment of the normal anchoring mechanism of the stomach. The role of the phreno-oesophageal ligament has been stressed by surgeons. It is normally a diaphanous structure which may atrophy with advancing age, permitting herniation to occur. Loss of muscle tone in the stomach may facilitate the upward passage of the cardia through the hiatus; this would explain the increased incidence of hiatus hernia in progressive systemic sclerosis, in which the musculature of the alimentary tract becomes atonic. After partial gastrectomy the mobility of the remaining portion of the stomach is increased, and this might well account for the frequency of small hiatus hernias and symptoms of reflux after this procedure.

Hiatus hernia may appear during pregnancy but disappear again after delivery, suggesting that it is not a congenital abnormality but one acquired as a consequence of the upward displacement of the stomach and possibly of hormonally induced gastric muscle hypotonicity occurring during pregnancy.

Clinical Presentation

Hiatus hernia may exist without producing symptoms, and it has been estimated that in only 25% of cases are these severe enough to cause the patient to seek medical advice. This accords well with the frequent finding of asymptomatic hiatus hernia on barium meal examination done for some other disorder. Furthermore, symptoms may abate spontaneously for long periods or even permanently, which of course makes assessment of the results of therapy difficult. Fluctuations in body weight and emotional state may determine their presence or absence or the disability they may cause.

Symptoms when present are usually caused by gastro-oesophageal reflux and its consequences, but with larger hernias obstructive symptoms may be encountered at the level of the diaphragm.

Gastro-oesophageal Reflux

These symptoms usually dominate the clinical picture in patients with sliding hiatus hernia. Most of the population has had occasional heartburn, belching, or acid-tasting fluid rising into the mouth at one time or another, and it is difficult on occasions to distinguish the point at which these become pathological.

Heartburn and Chest Pain.—Heartburn is a word commonly used by patients to describe a burning discomfort in the front of the chest sometimes radiating up into the neck or into the interscapular region. Many will deny that the discomfort

amounts to pain, but others experience severe pain, which may be difficult to distinguish from cardiac pain. The postural relationships of the pain are useful diagnostic pointers. Oesophageal pain often wakes the patient at night, and many have learned by experience that this can be corrected by sleeping propped up on pillows. Stooping or bending forward—when weeding the garden, sitting behind the wheel of a car, or in front of a television set—are characteristic aggravating factors. Swallowing hot or irritating fluids may aggravate the pain.

The differentiation of oesophageal from cardiac pain is not always easy, and the consequences of error are serious. No single feature of the pain provides a completely reliable guide, and the clinician must consider many factors in the history in coming to a diagnosis. The character of the pain is of some value, since oesophageal pain is commonly burning, while cardiac pain is often constricting in character.

Oesophageal pain may radiate to the arms, but pain down both arms is most frequently cardiac in origin. Pain brought on by emotional stress is as likely to be oesophageal as cardiac, and pain occurring after a heavy meal might well be anginal. Relief by antacids points strongly towards an oesophageal source for pain, but amyl nitrite seldom relieves oesophageal pain. If in doubt it is wise to assume that the pain is cardiac, at least for the first few days, bearing in mind however that recumbency and anticoagulant therapy may aggravate reflux oesophagitis and on occasion precipitate bleeding from the inflamed oesophageal mucosa.

Acid regurgitation into the mouth is a less common manifestation of gastro-oesophageal reflux, because the presence of gastric juice in the gullet frequently evokes a secondary peristaltic wave which sweeps it back into the stomach. Like heartburn, acid reflux has a postural relationship, occurring in recumbency or on stooping, and in its mildest form causes only a sour taste in the throat on waking. When more severe, large quantities of acid-tasting fluid rise into the throat without the physical effort of retching or straining. If regurgitation is copious choking attacks may wake the patient at night and aspiration pneumonia can occur.

Belching often complicates gastro-oesophageal reflux in hiatus hernia and usually results from air-swallowing to relieve heartburn. It may at times cause abdominal discomfort from distension and excessive flatus.

Anaemia and Bleeding

Inflamed oesophageal mucosa is friable—as every endoscopist knows. When the mucosa is inflamed the passage of food through the gullet may induce bleeding of sufficient degree eventually to cause anaemia. Furthermore, tablets of aspirin or phenylbutazone may remain in contact with the inflamed mucosa for a long enough period to induce bleeding and may precipitate haematemesis or melaena in patients with hiatus hernia.

One of the difficulties which may impede clinical diagnosis is the frequent paucity of dyspeptic symptoms in patients with reflux oesophagitis severe enough to cause bleeding. The bleeding may be intermittent, and therefore occult blood tests on the stools are not always positive. Hence reflux oesophagitis is often overlooked in elderly patients with iron deficiency anaemia and the diagnosis can only be verified directly by oesophagoscopy—which of course is not free from risk in the patients in this age group.

A further cause of acute bleeding in patients with hiatus hernia is a mucosal tear at the cardia (Mallory-Weiss syndrome). The presence of a small sliding hernia appears to predispose to the occurrence of such tears, presumably because this part of the stomach is then exposed to the considerable abdomino-thoracic pressure gradient which occurs during retching and vomiting.

Dysphagia

Dysphagia in hiatus hernia may be caused by stricture formation or less frequently by muscle spasm. Stricture is easily the most serious complication of reflux oesophagitis and is characterized by constant dysphagia in contrast to the much more variable difficulty encountered in patients with oesophageal spasm. The development of a tight stricture usually results in cessation of heartburn or acid reflux into the mouth, since the upward passage of gastric juice is impeded by the narrowing. Dilatation of the stricture may relieve dysphagia only for this to be replaced by heartburn and acid regurgitation. Radiological diagnosis of hiatus hernia may be difficult when stricture is present, because little barium passes down into the stomach, and the extent of the narrowing is then also difficult to define.

Dysphagia caused by oesophageal spasm is seldom severe enough to cause nutritional impairment. Heartburn is usually prominent and the differentiation from fibrous stricture by radiological or endoscopic means is not difficult. While the typical radiological appearances of corkscrew oesophagus caused by muscle spasm are readily recognized, the crenated, sawtooth outline of the gullet seen when the spasm is less marked must be distinguished from the filling defects of oesophageal varices.

Spasm commonly occurs in the middle and lower portions of the oesophagus, but a localized muscle contraction or thickening at the oesophago-gastric mucosal junction has been described in patients with hiatus hernia and has been called the lower oesophageal ring. This causes intermittent dysphagia and is visible as an annular narrowing just above the level of the diaphragm on x-ray films of the barium-filled oesophagus. At endoscopy such rings are often missed, but a shelflike fold of mucosa may be visible at the cardia. It is important that the rings should not be confused with fibrous strictures, since the disability they cause is seldom sufficient to warrant surgical intervention and the outlook with conservative treatment is good.

Obstructive Symptoms

These are confined to patients with larger hernias of the para-oesophageal or mixed type, which have often been known to be present for many years. Acute symptoms result from mechanical obstruction at diaphragmatic level with incarceration or strangulation. When the diaphragmatic hiatus remains tight food may impact at this level causing distension of the herniated portion of the stomach. Torsion of the stomach may occur with forward and upward rotation of the body through the diaphragm pulling the pylorus upwards. The greater curvature becomes the most cephalad portion of the stomach, the fundus falls back into the abdominal cavity, and the body of the stomach is left above the diaphragm. Acute angulation occurs at the junction of the body with the antrum where the stomach passes through the hiatus, and gangrene of the herniated stomach often rapidly supervenes from obstruction to the blood supply.

The onset of severe pain in the lower chest and upper abdomen, often associated with shock, frequently leads to confusion with cardiac infarction and fatal delay in instituting surgical treatment. Absolute dysphagia occurs but can be masked by constant retching. The herniated portion of the stomach is often enormously distended, and the presence of a fluid level behind the heart shadow is a useful radiological pointer to the diagnosis. The heart may be displaced by the distended stomach, and this positional change may give rise to electrocardiographic abnormalities, notably T wave inversion in leads III and AVF, which in conjunction with the clinical picture may lead to a mistaken diagnosis of posterior cardiac infarction.

Associated Disease

Oesophageal spasm has already been mentioned as a result of reflux oesophagitis. When it is severe and persistent it may cause pronounced hypertrophy and muscular wall of the oesophagus.

Gastric Ulcer.—Chronic gastric ulcer of the level of the diaphragmatic hiatus occasionally complicates the larger hiatus hernias due to trauma from food passing through the narrowing in this situation. After reduction of the hernia the ulcer usually heals rapidly.

Carcinoma of the Oesophagus.—Carcinoma of the gastric cardia has been reported in patients with hiatus hernia, but it seems doubtful whether this can be recognized as a true complication of reflux oesophagitis. These tumours are usually adenocarcinomas and not the squamous growths which might be expected if chronic irritation is an aetiological factor—as for example in oesophageal carcinoma after ingestion of corrosive poisons. Moreover, oesophagitis is frequently the consequence of a neoplasm in this situation interfering with the competence of the cardia. Bleeding from chronic reflux oesophagitis complicating hiatus hernia often causes iron deficiency and may so favour the occurrence of postcricoid carcinoma.

Management of Hiatus Hernia

The real difficulty which the management of hiatus hernia presents stems from the extreme variability of the disability it causes. On the one hand in many patients it is symptomless, but on the other hand it can lead to oesophageal stricture, which in the elderly carries a considerable mortality. It is not surprising that widely divergent views have been expressed about the relative merits of the numerous surgical procedures which have been used. Information is needed about the natural history of untreated hiatus hernia and the influence which the presence and severity of changes of oesophagitis seen at endoscopy have upon the outlook.

Before embarking on treatment adequate radiological studies are required to determine whether symptoms of reflux have been precipitated by delay in gastric emptying caused by duodenal or pyloric ulcer or by gastric carcinoma either near the pylorus or at the cardia.

Medical Measures

Two features of hiatus hernia which commend medical measures, at least at the onset, are its predilection for the middle aged and elderly and the mildness and tendency to spontaneous remission of the symptoms in many cases. The aims of medical treatment are fourfold:

- (1) To minimize reflux of gastric juice into the gullet.
- (2) To neutralize the acid of the gastric juice.
- (3) To protect the oesophageal mucosa by the use of demulcents.
- (4) To deal with any superadded emotional tension.

Since heartburn is precipitated by lying flat and by stooping and bending forwards, and since oesophageal acidity measurements reveal these movements to be accompanied by acid reflux, it seems logical to ask the patient to avoid such positions as far as possible. Sleeping propped up on pillows affords relief early in the night, but sooner or later the patient slips down and reflux occurs. For this reason and also to avoid the slight abdominal compression which occurs in the lying posture it is preferable to tilt the whole bed using 4–8 in. (10–20 cm.) blocks (one or two builder's bricks) under the head of the bed. Should the patient slide down the bed the patient is unaltered. In severe cases a cardiac bed may be required, but these are rare. The avoidance of constricting clothing around the abdomen is usually recommended but often

ignored by the obese. Many patients with hiatus hernia develop symptoms of reflux after gaining weight, and in these weight reduction gives striking symptomatic relief. Indeed, the major importance of diet in hiatus hernia is in the control of obesity, and a strict gastric diet has little value and may cause harm by increasing obesity. Very hot drinks and hard foods such as toast may cause pain when swallowed, while other patients find foods such as onions and cucumber—which may remain in the stomach for long periods exciting acid secretion—cause heartburn and are best avoided.

Antacids usually give relief from pain in reflux oesophagitis, and treatment should aim at neutralizing the gastric as well as the oesophageal contents for as long as possible. Aluminium hydroxide gel remains one of the most effective remedies, as it also has a demulcent action. Anticholinergic drugs have no place in the treatment of reflux oesophagitis, since they not only relax the oesophago-gastric sphincter and thus favour reflux but abolish oesophageal peristalsis and so allow any gastric juice to remain in the gullet for long periods during the night.

In patients with severe symptoms milk with added aluminium hydroxide dripped continuously into the mid-oesophagus for 7–10 days is often strikingly effective in relieving symptoms and improving oesophagitis. The patient should be propped up to reduce the risk of aspiration into the lung.

Polymethyl siloxane is a silicone preparation which reduces surface tension, thus preventing foaming by allowing coalescence to form a single large gastric air bubble which is more easily expelled and in the process less likely to carry gastric juice up into the gullet. Furthermore, it has some coating action and may protect the inflamed oesophageal mucosa. To be of benefit it must be given regularly in doses of 250 mg. and is combined with antacids in the preparation Asilone.

Oxethazine is a surface anaesthetic, which is usually combined with an antacid in preparations such as Mucaine. When pain from oesophagitis is refractory to other measures it is frequently effective, particularly during pregnancy. Caution is necessary, since relief of pain does not imply improvement in oesophagitis, which may actually progress. Use of the drug is therefore best confined to patients who have pain with minimal changes at oesophagoscopy, and it is inadvisable to give it for long periods, since a stricture may quietly develop.

Finally the patient's emotional state may determine his reaction to his oesophageal symptoms. Anxious patients have a particular fear of chest pain, and reassurance together with tranquillizing drugs may help to restore to its true perspective discomfort due to mild reflux.

Retrospective surveys of patients with hiatus hernia managed conservatively suggest that ten years later 60% remain symptom-free or much improved, but this figure falls to 40% if endoscopic evidence of oesophagitis is present. Medical measures are ineffective in giving adequate relief in a minority of patients and surgical treatment has to be considered.

Surgical Treatment

If a tight stricture and fibrotic shortening of the gullet are absent the simplest surgical procedure is reduction of the hernia and tightening of the hiatus by suturing posteriorly and repairing the phreno-oesophageal ligament to restore the abdominal segment of oesophagus. The results of this type of operation vary considerably in different surgical hands; the recurrence rate of herniation is usually 10–30% and an even greater proportion have radiologically demonstrable reflux. This has led other surgeons to devise ways of reconstituting the oesophago-gastric angle and some combine repair with vagotomy-pyloroplasty. Symptomatic relief does not correlate closely with radiological findings after repair, and fortunately benefit persists in many in whom herniation and reflux are still present

—suggests that at least symptomatic improvement might be achieved without operation. While none would dispute that surgery often succeeds where medical measures have failed, it is also true that surgical series often contain patients in whom these measures have never been given a fair trial.

The selection of patients with hiatus hernia for surgical treatment depends on the degree of disability and the physical condition of the patient. The younger and fitter the patient the more readily should surgery be considered.

The following are indications for surgical treatment of hiatus hernia:

(1) Dissatisfaction of the patient with symptomatic relief after six months' conservative treatment or unwillingness to continue such treatment. Certain patients have severe pain with only minimal evidence of oesophagitis, and surgery should not be withheld simply because of the absence of gross pathological changes.

(2) The persistence of oesophagitis after six months' medical treatment and the development of peptic ulcer in the oesophagus or in the stomach at the level of the hiatus.

(3) Signs of a stricture developing. If mild this may respond satisfactorily to a simple reparative operation, but if it is tight and causing nutritional impairment resection with interposition of a jejunal loop or taking the stomach into the chest is mandatory.

(4) Recurrent bleeding in a younger person is best treated surgically, but the elderly often do well with conservative measures in such a situation.

(5) The occurrence of aspiration pneumonia.

(6) Incarceration or strangulation is an urgent indication for operation.

Unfortunately hiatus hernia is common in the older age group, where other disease, notably cardiac ischaemia, often coexists. Here the risk of operation, intrathoracic or intra-abdominal, might be judged too great even in the presence of the above indications and no choice is left but to continue medical measures.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Collapse after Triple Antigen

Q.—It was stated in an answer to a question¹ that collapse occurring one to four hours after immunization with triple antigen is not an anaphylactic reaction. What is the evidence for that statement?

A.—The statement that collapse after triple antigen is not an anaphylactic reaction was made on the following grounds:

(1) None of the physicians concerned with the treatment of reported cases of "collapse" have associated the condition with anaphylaxis.²⁻⁴ Similarly, Sir Graham Wilson,⁵ who examined the literature and perused Ministry of Health files on complaints, does not suggest that any of the reactions were anaphylactic in origin.

(2) Respiratory embarrassment, swelling of lips and eyelids, and restlessness and cyanosis are common features in a severe anaphylactic reaction. They do not occur in "collapse." A collapsed infant is extremely pale, limp, listless, and lifeless.

(3) The interval between injection of antigen and onset of anaphylactic reaction is a matter of seconds or of only a few minutes, but there is usually an interval of three to four hours and never less than one hour between pertussis vaccination and the onset of collapse.

(4) Collapse occurs as frequently after the first as after the second or third injection of pertussis vaccine. Though children who have collapsed after receiving pertussis vaccine are prone to do so after a repeat injection, a high proportion are unaffected by the second dose. Collapse is not therefore the result of sensitization.

(5) The incidence of collapse may be substantially reduced by merely halving the dose of pertussis vaccine given.⁶ It may be, therefore, that the dose of vaccine given in relation to body weight is an important factor. Anaphylactic reactions are not greatly affected by these considerations.

I do not know of any detailed studies carried out on infants with a history of "collapse" after triple antigen.

Muscular Spasms in Paraplegia

Q.—Can anything be done in a patient aged 86, suffering from paraparesis of the lower limbs, to reduce muscular spasm in one thigh which has increased considerably since the femur was fractured and operated on eight months ago?

A.—Flexor spasms may be initiated in patients with paraplegia by a painful lesion or an irritative focus such as a pressure sore. These spasms, however, are usually bilateral. It would seem most likely in this case that the spasm is associated with the lesion in the hip.

On the whole, treatment is unsatisfactory. A physiotherapist should try gentle stretching to overcome the spasm, and heat and massage may help. If the patient is develop-

ing a flexion contracture of the hip on the affected side an effort should be made to nurse him in the prone position. Much perseverance is needed, but sometimes the results are good. If the flexor spasms are occurring at the knee joint the use of light-weight plastic splints, as described by Brennan,¹ can be helpful in overcoming spasm and preventing permanent contractures developing.

Oral Diuretics and Hyperuricaemia

Q.—Some elderly patients develop high blood uric-acid levels and gout-like pains while taking chlorothiazide or frusemide. Is there an effective oral diuretic which does not have these effects, or, alternatively, should a uricosuric agent be given with the diuretics?

A.—It is recognized that most oral diuretics—all the thiazides, chlorthalidone, quinethazone, ethacrynic acid, and frusemide—may cause hyperuricaemia and precipitate attacks of clinical gout in susceptible subjects. Triamterene, which has a different mode of action, does not have this effect and can be used in these circumstances. Triamterene is, however, a relatively weak diuretic on its own and often requires the addition of one of the other diuretics to obtain a satisfactory response.

It is also possible to prevent diuretic-induced hyperuricaemia and to relieve the symptoms of gout by giving a uricosuric agent such as probenecid or sulfinpyrazone along with the oral diuretic.¹⁻³

Gastroenterological Conference

A Case of Crohn's Disease in a Patient with Treated Adult Coeliac Disease

DEMONSTRATED AT THE ROYAL POSTGRADUATE MEDICAL SCHOOL

Clinical History

Professor C. BOOTH: This patient (Case No. 204058; P.M. No. 11730) was an Irish housewife aged 34 at the time of death in 1966. In 1957 she had had an attack of acute glomerulonephritis one week after full term normal delivery of her second baby. She had completely recovered from this illness.

On 7 September 1964 she was admitted to Hammersmith Hospital under the care of Dr. Cope complaining of diarrhoea, swelling of the ankles, loss of weight, and amenorrhoea. The stools were loose, pale, and greasy, and she had had as many as 10 motions a day during the previous 18 weeks. Swelling of the ankles had been present for nine weeks. She had also recently noticed pins and needles and stiffness in her fingers.

On examination she was thin and markedly wasted, weight 103 lb. (44 kg.). There was marked oedema extending from the ankles up to the thighs and on to the abdominal wall. There was clubbing of the fingers. The blood pressure was 9/70 mm. Hg, the pulse rate regular, and the heart normal. The chest and abdomen were normal. The central nervous system was normal except that both the Chvostek and the Trousseau signs were positive.

Investigation at this stage showed the haemoglobin to be 9 g./100 ml., P.C.V. 35%; stained blood films showed evidence of macrocytosis and the bone marrow was megaloblastic. The serum folate was 1 $\mu\text{g.}/\text{ml.}$ (normal $>6 \mu\text{g.}/\text{ml.}$) and the serum B_{12} 200 $\mu\text{g.}/\text{ml.}$ (normal range $>140 \mu\text{g.}/\text{ml.}$). The blood urea was 14 mg./100 ml., the bicarbonate 29, sodium 142, potassium 2.7, and chloride 103 mN. The calcium was 2.7, magnesium 1.7, and phosphate 1.3 mN. The alkaline phosphatase was 32 King-Armstrong units; the serum albumin was 1.0 and globulin 2.3 g./100 ml. A barium meal showed marked dilatation of the small bowel loops.

A jejunal biopsy showed a completely flat mucosa under the dissecting-microscope, and on histological examination there was subtotal villous atrophy. Absorption tests were then carried out. The faecal fat excretion was 72 g./day, and the fat excretion in the urine was 1.1 g. following a 25 g. dose. A glucose tolerance test was done; the blood glucose levels at 15-minute intervals after an oral dose of 50 g. glucose were 63, 70, 75, 70, and 55 mg./100 ml. The Schilling test showed 1.3% of the oral test dose excreted (normal range 10%; test dose was 1 $\mu\text{g.}$ of radioactive vitamin B_{12} given with intrinsic factor).

Response to Treatment

In view of this evidence of intestinal malabsorption and the finding of subtotal villous atrophy in the jejunal biopsy, a diagnosis of adult coeliac disease was made. On 12 September treatment was started with a gluten-free diet. She made an excellent response to the gluten-free diet clinically, biochemically and histologically. Within a month there had been a marked improvement in the appearance of the jejunal biopsy,

the mucosa had reverted to a convoluted appearance, and the surface cells had become normal in height (Chart). She was discharged home on 3 October taking a gluten-free diet, folic acid 5 mg. daily by mouth, Calcium-Sandoz two tablets three times daily, and calciferol 100,000 units once monthly. By June 1965 she was feeling very well. Her weight had increased by 3 stones (18 kg.), her haemoglobin was now 12.2 g./100 ml., the calcium 5.2 mN., the phosphate 1.9 mN., and the alkaline

phosphatase had fallen to 10 King-Armstrong units. The steatorrhoea was markedly improved, the faecal fat excretion having fallen to 6.9 g./day. In November 1965 her periods returned after 18 months' amenorrhoea.

Six months later, however, she was readmitted to Hammersmith Hospital with vaginal bleeding, fever, abdominal pain, diarrhoea, and vomiting. She had clearly lost weight. She was wasted and oedematous, with a dry mouth and tongue. The Chvostek and Trousseau signs were again positive. There was tenderness in the lower abdomen.

Investigations revealed a haemoglobin of 11.1 g./100 ml., but the sternal marrow was now normoblastic. The white cell count was elevated at 14,000/cu. mm. Her blood urea had risen to 155 mg./100 ml.; electrolytes were as follows: sodium 132, potassium 3.1, chloride 99, and bicarbonate 27 mN.; calcium was 3.8, magnesium 1.2, and phosphate 1.7 mN. The alkaline phosphatase was 14 King-Armstrong units. The serum albumin had again fallen to 1.3 g./100 ml. She was treated with intravenous fluids and on 23 March aborted an 18-week twin pregnancy. Following abortion, however, the fever, diarrhoea, and vomiting persisted, and by 3 April 1966 she had developed a skin rash. In view of her severe deterioration she was started on treatment with prednisone 20 mg. daily on 7 April, and on 14 April a barium meal was carried out. This showed multiple areas of constriction of the mid and distal small intestinal loops and it was concluded that she might be suffering from lymphoma of the intestine.

FIG. 1A.—Jejunal biopsy before treatment. Subtotal villous atrophy is seen with thin covering epithelium. (Average cell height 13 microns.) (H. and E. $\times 160$.)

FIG. 1B.—Jejunal biopsy three months after treatment. Severe partial villous atrophy is still present, but covering epithelium is almost normal. (Average cell height 32 microns.) (H. and E. $\times 160$.)

FIG. 2.—Macroscopic appearance of jejunum of the junction of stricture and relatively normal bowel. The stricture (left) shows severe submucosal thickening and has a "cobblestone" appearance.

FIG. 3.—Jejunum showing ulceration of the mucosa and gross thickening of the submucosa. A chronic inflammatory infiltrate—occasionally arranged focally—is seen as well as lymphangiectasia. Covering mucosa with an intact muscularis mucosa can be seen on the left. (H. and E. $\times 45$.)

FIG. 4.—Fissure lined by granulation tissue extending deeply into the submucosa. (H. and E. $\times 45$.)

FIG. 5.—Spleen showing atrophy. Hardly any red pulp is seen.

FIG. 6.—Part of right hepatic vein showing organizing thrombus near the vessel wall and recent thrombus towards the lumen. (Elastic van Gieson. $\times 65$.)

Exploration

On 19 May 1966 an exploratory laparotomy was carried out. This revealed many areas of thickened and reddened bowel extending from approximately 2½ ft. (75 cm.) distal to the duodeno-jejunal flexure to the terminal ileum. There were similar lesions in the transverse colon. The macroscopic appearances suggested Crohn's disease. No operative procedure was carried out and no biopsy was taken. Treatment was continued with intramuscular methyl prednisolone 60 mg. daily, but there was no response. Her haemoglobin fell and she required blood transfusions on four occasions. She was given albumin infusions in an attempt to correct her hypoproteinaemia, but the serum albumin never rose higher than 1.5 g./100 ml. On 28 June 1966 she developed signs of consolidation and cavitation in the right upper lobe. Sputum cultures at this stage yielded *Pseudomonas pyocyanea*. Despite treatment with gentamicin and polymyxin her condition steadily deteriorated until she died on 4 July 1966.

Clinical Diagnosis

- (1) Adult coeliac disease treated with gluten-free diet.
- (2) Crohn's disease.
- (3) Lung abscess.

Biopsy Findings

Dr. J. S. STEWART: When we first examined this patient's untreated proximal intestinal mucosa under the dissecting-microscope it was about as flat as any we have seen. Histologically (Fig. 1A), the most striking feature was the severe abnormality of the epithelial surface cells, which showed many signs of damage. The simplest way to quantitate this is to measure the reduced surface cell height, in this instance 13 µ, the normal range in our series being from 29–36 µ. The other salient features are the increased mucosal thickness and the dense chronic inflammatory cell infiltration.

One week after she had started taking a gluten-free diet a repeat jejunal biopsy showed a dramatic increase in the surface cell height from 13 to 22 µ. Macroscopically it was still almost completely flat. Repeat biopsy at two months showed a partially convoluted appearance. At three months (Fig. 1B) the mucosa showed only convolutions.

This patient kindly allowed us to do weekly biopsies for four weeks and then again at two and three months. While the surface cell height rose rapidly within the first few weeks and reached normal levels at two months, the macroscopic appearance showed no significant change until four weeks after the start of gluten withdrawal. At three months it was not yet quite normal.

At that time we were engaged in a collaborative study with Professor Pearce's department of histochemistry to assess the significance of the enzyme changes known to occur in the intestinal mucosa of patients with idiopathic steatorrhoea. Dr. Ernst Riecken, working with Professor Pearce, did the histochemistry and drew attention to certain changes in the distribution of acid phosphatase in the epithelial surface cells. In this patient, before the start of her gluten-free diet, the two dominant features were the diffuse distribution and the reduction in the intensity of the staining. This diffusion appeared to be due to rupture of the lysosomes, the intracellular organelles containing lytic, destructive enzymes. It is probable that the rupture of the lysosomal membranes accounts for much of the damage in the epithelial surface cells. We think that this rupture is in turn brought about by the direct action of gluten on the cells.

To summarize these findings, serial biopsies provided evidence of gluten sensitivity in this patient by demonstrating rapid return of the proximal intestinal mucosa towards normal after withdrawal of gluten.

Post-mortem Findings

Dr. E. OLSEN: Permission for a limited necropsy only was granted. The body was that of a wasted female. Bilateral ankle oedema and mild finger-clubbing were present. The laparotomy scar had healed.

The mid and distal parts of the *jejunum* and the proximal part of the *ileum* showed multiple tubular strictures (Fig. 2) of varying lengths (longest about 30 cm.). In these the wall was thick. The mucosa had a "cobblestone" appearance and was for the most part devoid of epithelium. Adjacent to the "cobblestone" appearance flat mucosa was seen under the dissecting-microscope. The gut between the strictures was predominantly normal, but patches of flat epithelium were also found. The remainder of the gastrointestinal tract was normal.

On histology the mucosa was largely ulcerated (Fig. 3), but flat epithelium was seen in patches. Pyloric gland metaplasia was also seen. The submucosa showed gross thickening consisting mostly of fibrous tissue, but areas of oedema with lymph-angiectasia were found. There was a severe chronic inflammatory infiltrate as well as focal collections of lymphoid tissue. Fissures (Fig. 4) lined by granulation tissue extended into the submucosa. The muscle coats showed inflammatory cells and the serosa was thick and fibrous. Adjacent lymph nodes were normal. Despite the absence of giant cell granulomas a diagnosis of Crohn's disease was made.

The right *lung* weighed 800 g. (normal upper limit 400 g.) and the left *lung* 650 g. (320 g.). The bronchi contained greenish pus. The lungs showed infarct-like areas and were oedematous and patchily consolidated. An abscess measuring 4 cm. was found in the right upper lobe. A recent thrombo-embolus was found in a segmental pulmonary artery. Histology showed widespread bronchopneumonia. *Pneumocystis carinii* was identified. Small vessels occluded by thrombi were found near the abscess.

The *spleen* was atrophic and weighed 60 g. (normal 100–150 g.). Histology showed no red pulp (Fig. 5). Reticulo-endothelial cells in the trabeculae were stuffed with iron.

The *liver* weighed 1,300 g. The right hepatic vein showed a thrombus (Fig. 6) which did not occlude the lumen. Two areas of intense congestion were seen in the right lobe of the liver. Histology of these areas showed sinusoids distended with blood. Elsewhere the liver showed severe fatty change. Iron was found in abundance in Kupffer and liver cells. Some smaller intrahepatic veins were occluded by organized thrombi. The thrombus in the right hepatic vein showed varying degrees of organization and was capped by very recent thrombus.

The right *kidney* weighed 140 g., the left 122 g., and showed tiny abscesses.

The *parathyroid glands* showed predominantly chief-cell hyperplasia. The *adrenal glands* weighed 4 g. each (normal 6–7 g. each) and showed lipid depletion.

The *uterus* still showed evidence of pregnancy three months after abortion.

Pathologist's Diagnosis

- (1) Idiopathic steatorrhoea (consistent with adult coeliac disease).
- (2) Crohn's disease.
- (3) Renal and lung abscesses.
Bronchopneumonia.
Pulmonary thrombo-embolism.
Pneumocystis carinii.
- (4) Hepatic vein thrombosis.
- (5) Splenic atrophy.
- (6) Secondary parathyroid hyperplasia.

Discussion

Professor BOOTH: This is an extremely interesting problem. I should stress that we haven't previously seen a patient like this who presented originally as an adult coeliac and who then developed Crohn's disease.

It has been suggested that coeliac disease may be due to a congenital peptidase defect in the intestinal mucosa. Gluten is normally digested in the lumen of the gut, probably not entirely to amino-acids, but also to some extent only as far as peptides. In coeliac disease a toxic peptide may then diffuse into the cell, where there is a deficiency of an intracellular peptidase which normally digests it. The toxic peptide may then rupture the lysosomal membrane, allowing the diffusion of autolytic enzymes throughout the cell with subsequent destruction of the intestinal cell. It has been suggested that the condition may be inherited as an incomplete dominant. There are, however, facts which conflict with this simple theory. Firstly, a discordant pair of identical twins, one with the disease and one without, has been described. Secondly, there is the failure of response to a gluten-free diet in some patients. Thirdly, there appears to be some association of adult coeliac disease with malignancy. The practical point is that the simple genetic theory of coeliac disease in the adult as a peptidase defect doesn't fit all the patients we see, and certainly not the patient we've seen this morning, for the necropsy findings suggest Crohn's disease.

The splenic atrophy found in this patient occurs very frequently in this condition and produces a characteristic haematological picture with Howell-Jolly bodies in some patients. We missed the pneumocystis—an interesting finding, sometimes seen in patients with lymphoma as well as in patients who have been treated with corticosteroids. The liver changes are also extremely interesting. The parathyroid hyperplasia is presumably secondary to the chronic steatorrhoea.

Intestinal Lesion

Dr. B. MORSON: The pathological diagnosis of the gut lesion in this patient is probably Crohn's disease. I haven't much to add to Dr. Olsen's excellent description of the gross pathology and the microscopic appearances, except to emphasize the value of fissuring in the diagnosis. What I mean by fissuring is the presence of intercommunicating cracks or crevices in the cobblestone mucosa, which was confirmed histologically. I regard this morphological feature as supporting the diagnosis of Crohn's disease here. The other macroscopic appearances in general are certainly consistent with this diagnosis. The first thing that struck me in the microphotographs was the notable widening of the sub-mucosa, which was filled with inflammatory infiltrate accompanied by oedema and lymphectasia. Pyloric gland metaplasia is very commonly present in surgical specimens and necropsy material of Crohn's disease. Was there any neuromatous hyperplasia in the gut wall? That, I think, would be helpful in the diagnosis.

Dr. OLSEN: No, none was found. What we did find, however, was hyperplasia of the actual ganglion cells.

Dr. MORSON: This is quite common in Crohn's disease—it is a Schwann cell proliferation, and the nerves appear like large knotted structures, but I doubt that this is pathognomonic.

Professor BOOTH: I don't think it is either, because Dr. Williams will remember a patient some years ago with chronic ileal obstruction due to a simple stricture of the ileum which was associated with the same neuromatous picture. Does anybody disagree with Dr. Morson that this is Crohn's disease?

Professor D. MOLLIN: Did anyone look for acid-fast bacilli?

Dr. OLSEN: Yes, we did in one section only, but in the absence of granulomata this investigation was not pursued further.

Professor BOOTH: Could it be tuberculosis?

Dr. MORSON: I don't think so.

Professor BOOTH: Why?

Dr. MORSON: There are none of the morphological signs of tuberculosis in the form of collections of epithelioid cells and giant cells. It's true that the diagnosis of tuberculosis can be made in the absence of these, but there are usually areas of necrosis in which you may find tubercle bacilli. The other point is that the lymph nodes were normal, and this is unlike tuberculosis.

Dr. OLSEN: Professor Booth, you mentioned earlier that the gut lesions look to you like inflammatory lumps, but I considered these to be Crohn's disease. Did you in fact refer to the four cases which have been described by Goulston *et al.*? These showed non-specific jejunitis associated with coeliac disease. Two of these patients responded to a gluten-free diet, but this was non-specific proximal jejunitis, quite different from our patient today, who showed the more specific pathological changes of Crohn's disease.

Professor BOOTH: One might add that in our family studies of coeliac disease I have seen one patient with coeliac disease whose brother had Crohn's disease. Professor Mollin, would you like to make any further comments?

Professor MOLLIN: There are only two points. One concerns the Figlu tests, and I think Dr. Hoffbrand ought to talk about that. The other point is about the amount of iron in her tissues. She doesn't seem to have suffered from iron deficiency anaemia at any stage, although she suffered from idiopathic steatorrhoea and had been pregnant. At necropsy there was iron everywhere—you could see it quite readily in the liver parenchyma, which is definitely abnormal.

Professor BOOTH: How many pints of blood did she have?

Dr. G. HEPNER: Between March and her death in June she had 22 pints.

Dr. OLSEN: I think transfusion could partly explain the excess iron, but in addition to this there was hepatic vein thrombosis. In the slide I showed it did not obstruct the lumen of the main vein on the right side, but there was also widespread and long-standing intrahepatic venous occlusion within the right lobe of the liver. Although both lobes of the liver were strongly positive for iron, the right lobe (with widespread venous occlusion) showed slightly more iron. So there are probably two components at least which could explain the iron in the liver.

Professor BOOTH: Shall we take the other point about the Figlu test?

Histidine Metabolism

Dr. V. HOFFBRAND: This patient was most unusual for a patient with idiopathic steatorrhoea in her handling of the amino-acid histidine. Just to remind you of the metabolic pathway, histidine is broken down in the body to the amino-acid glutamic acid, but in the presence of folate deficiency the pathway is blocked at the level of formiminoglutamic acid (Figlu) and this compound appears in the urine. Patients with untreated idiopathic steatorrhoea almost invariably excrete raised amounts of Figlu after an oral dose of histidine because of folate deficiency. On her admission in 1964 this patient excreted Figlu but also excreted urocanic acid, the precursor of Figlu in the histidine breakdown pathway. Urocanic acid excretion is not directly related to folate deficiency, but is due to deficiency of the hepatic enzyme urocanase, and this occurs in protein deficiency and in liver disease. Urocanic acid excretion was reported in 1961 by Whitehead and Arnstein² in children with kwashiorkor. Studies here with Dr. Neale on postgastrectomy patients with hypoproteinaemia have shown that they also excrete large amounts of urocanic acid. In 1964 this patient was, as Professor Booth has said, hypoproteinaemic,

and this is the probable explanation of why she excreted urocanic acid as well as Figlu. When she was treated with a gluten-free diet and folic acid, both compounds disappeared from the urine—Figlu because folate deficiency was corrected, and urocanic acid because her protein deficiency improved. When she was subsequently admitted in 1966, she was found to be excreting vast amounts of urocanic acid. The normal range is up to approximately 6 mg. in eight hours after a 15 g. oral loading dose of histidine, and she was excreting more than 2,000 mg. in eight hours. She was already receiving folic acid in large doses, her marrow was normoblastic and Figlu excretion was normal, so this was certainly nothing to do with folate deficiency. However, she was severely hypoproteinaemic, and when she was given albumin infusions urocanic acid excretion fell to 200 mg. in eight hours, but it was never completely corrected, and just before she died she was still hypoproteinaemic and excreting over 1,000 mg. of urocanic acid in eight hours. I wonder if protein deficiency could explain the fatty changes found in the liver at necropsy.

Professor MOLLIN: Could I ask Dr. Hoffbrand one question? Would you think that if a patient with idiopathic steatorrhoea excretes urocanic acid this is a sinister sign?

Dr. HOFFBRAND: We have found raised urocanic acid excretion in only three patients among over 60 with idiopathic steatorrhoea examined. Two of these three, including the present patient, suffered from severe hypoproteinaemia, and both died. The third probably had liver involvement by an associated virus infection and he is now well and does not excrete urocanic acid.

Malignant Disease and Steatorrhoea

Dr. J. HOBBS: Between 12 and 16 April 1966 (before laparotomy on 19 May) the serum alkaline phosphatase rose from 12 to 21 King-Armstrong units, the 5-nucleotidase from 12 to 39 i.u./l., the isocitrate dehydrogenase to 12 i.u./l. and the bromsulphalein retention to 47%. In retrospect this is probably when the hepatic venous thrombosis occurred.

Turning to the lysosomal hypothesis Allison³ has reviewed the evidence that lysosomal D.N.A.-ase can damage D.N.A. and might thereby result in neoplastic mutation. It is therefore very interesting that there is a 15% incidence of malignant disease associated with idiopathic steatorrhoea.

Professor BOOTH: The association with malignant disease is also interesting in relation to the lymphoreticular atrophy and the small spleen. The Bristol workers have claimed that the lymph nodes are small in adult coeliac disease. Did we have immune globulin studies in this lady?

Dr. HOBBS: Three months before death the serum levels were γ G 540, γ A 150, and γ M 85 mg./100 ml. She did not show the low γ M found in 18 out of 60 of your patients with coeliac disease.

Dr. G. NEALE: Dr. Hobbs suggested that rupture of the lysosomes might lead to neoplastic mutation. In coeliac disease the epithelial cells of the small intestine suffer direct damage by gluten, but the associated malignancy is not usually an adenocarcinoma of the small intestine. It is, in fact, malignant lymphoma.

Professor BOOTH: The commonest malignancy is a reticulosis, but the next commonest appears to be carcinoma of the oesophagus.

Dr. STEWART: Complementary to Professor Mollin's point about urocanic excretion in idiopathic steatorrhoea, this is perhaps a bad prognostic sign. Certainly, hypoalbuminaemia appears to be. From a clinical point of view, the only other patient who presented predominantly with oedema was a lady who died of idiopathic steatorrhoea without, apparently, any other complicating disease.

Professor BOOTH: They tend to do badly, don't they. This is quite true.

Dr. M. BERRY: Has anyone digested gluten with pepsin, trypsin and then administered the digest to patients with idiopathic steatorrhoea?

Professor BOOTH: Yes, this has been done with peptic and tryptic digests and this material retains its toxic quality. However, that material is digested further with hog intestinal mucosa, then the toxic quality is lost.

Bone Changes

Dr. A. DOUGLAS: I wonder if I might ask two questions—firstly, it's very interesting that she was given 60 mg. of prednisone per day, and she in fact did not become Cushingoid. Is that the usual sort of thing in patients with Crohn's disease? Secondly, she had a low serum calcium, very high alkaline phosphatase, a Chvostek and Trousseau sign, and parathyroid hyperplasia, yet apparently no radiological changes.

Dr. G. JOPLIN: I would agree that attention should be drawn to the disproportion here between the alkaline phosphatase and serum calcium on the one hand and the bone changes on the other hand. This is by no means rare. In a series of about 80 patients that Dr. Gilbert Thompson and I did some combined studies on, we found that there were quite a number of patients who did show this disproportion, and I think it is important to recognize that bone changes need not be radiologically obvious before the diagnosis of osteomalacia can be made. In fact in this particular patient we measured the 24-hour strontium space, and the result was very high indeed. This tallies with the high alkaline phosphatase and the low serum calcium, and this really prompts the question to the pathologists—what about the bones at necropsy?

Professor BOOTH: Well, what about the bones?

Dr. OLSEN: They appeared normal, macroscopically and microscopically.

Dr. JOPLIN: That's very difficult to accept, unless there had been some effective treatment. How long had the patient been on vitamin D?

Dr. HEPNER: She'd been put on vitamin D in October 1964 and she'd been taking oral calciferol intermittently until she was admitted in March 1966, and she'd also been on calcium sulphate.

Professor BOOTH: That explains the normality of the bones.

Dr. MORSON: Could I just ask one more question? Was there any alteration in the Paneth cell population in the small intestinal biopsy?

Dr. OLSEN: There was no alteration at all.

Dr. J. W. LAWS: The radiological changes were interesting. In the second barium follow-through examination, multiple stenosing lesions with an abnormal mucosal pattern were shown. Knowing the patient had idiopathic steatorrhoea and knowing that lymphoma is commonly associated with it, we thought the changes might be due to lymphoma. In fact, the appearances fit in perfectly well with Crohn's disease—which would have been our diagnosis if we had not been put off by knowing that the patient had proved idiopathic steatorrhoea.

Steatorrhoea tends to make the barium flocculate, when it is difficult to show the anatomical abnormality very clearly. Flocculation isn't a very useful sign, as it occurs in steatorrhoea of any cause.

Dr. OLSEN: One very often sees finger clubbing with steatorrhoea and coeliac disease. May I ask the mechanism of this finger clubbing? It has at one time been said it is associated with vitamin deficiency. But what is the actual mechanism?

Professor J. GOODWIN: This is a question which needs a very long answer. In patients with cyanotic congenital heart diseases there is an overgrowth of the terminal phalanx and an excess of capillaries. This sort of thing tends to happen elsewhere in the body as well, in the renal glomeruli, for example.

and reflects perhaps a generalized capillary abnormality or excessive local capillary development as a result of reduced arterial saturation. It differs from the clubbing that develops in chest disease due to excessive reduced apoferritin. The clubbing that I cannot understand at all is the clubbing in bacterial endocarditis, left atrial myxoma, and coeliac disease.

Professor BOOTH: Thank you very much. We must conclude this was a patient with adult coeliac disease who developed Crohn's disease, whatever that may be.

We are grateful to Professor J. P. Shillingford and Dr. E. D. Williams for assistance in preparing this report, and to Mr. W. Brackenbury for the photomicrographs.

NEW APPLIANCES

Repeated Haemodialysis with a Straight Silicone Rubber Cannula

Dr. J. B. HAWKINS, registrar, and Dr. B. H. B. ROBINSON, consultant physician, Renal Unit, East Birmingham Hospital, write: The Quinton-Scribner Silastic/Teflon cannula (Quinton, Dillard, and Scribner, 1960; Quinton, Dillard, Cole, and Scribner, 1962) has made possible the widespread use of repeated haemodialysis for the treatment of chronic renal failure. This system is also valuable in the management of those patients with acute renal failure for whom repeated or frequent haemodialysis is necessary (Clark

Renal Unit for nine months. It is easy to clear of thrombus, relatively simple to insert, and cheap.

The cannula (Fig. 1) is made from medical-grade silicone rubber tubing (Esco Rubber Ltd.) similar in size to that used for conventional cannulae. To this is attached a silicone rubber wing 2.5 cm. wide by means of an appropriate adhesive (Dow Corning silicone type A). The edges of the wing slope away from the vessel tip at an angle of approximately $22\frac{1}{2}^\circ$. Small holes may be

Thus a Teflon tip can be inserted higher up the same vessel with a minimum of tissue disturbance. After cannulation of artery and vein a single Teflon connector is used to produce an arteriovenous shunt (Fig. 2).

CLINICAL EXPERIENCE

Specially moulded cannulae available commercially are expensive. This cannula was originally designed as a cheap device for managing hypercatabolic acute renal failure by repeated haemodialysis, and has proved entirely satisfactory. It is relatively simple to insert compared with the conventional cannula, and is easy to clear of clot. There is a possible danger, however, that the over-vigorous passage of a declotting catheter might dislodge the vessel tip or damage the vessel wall. So far we have not had this experience. Once inserted, the cannula will withstand a direct pull in excess of 2.5 kg., sustained or intermittent, without dislodgement of the vessel tip.

Encouraged by the success of this cannula for acute cases, we have made use of it in several patients undergoing long-term intermittent haemodialysis. Initial results are good. Although specially prepared silicone rubber is not used for these cannulae, clotting episodes are no more frequent than with Quinton-Scribner shunts. Blood flow rates through Kiil dialysers are, on average, higher than with curved cannulae, though direct comparison is clearly not possible.

This shunt has the disadvantage that it cannot be placed as far distally in the limb as the Quinton-Scribner shunt, but an exit hole 4 cm. above the proximal wrist crease has been found satisfactory, and we believe that with either type of shunt it is better to cannulate the vessel well above this in order to minimize movement due to flexion and extension at the wrist. We have not found that a 60° step at the exit site is necessary, and its absence facilitates placing of the cannula.

The original pair of cannulae inserted for intermittent dialysis are still in use for home dialysis seven months after insertion, while three other pairs are in use after approximately five months. Only one pair of cannulae has required reimplantation (as a result of infection).

FIG. 1

and Parsons, 1966). The system suffers from the disadvantage that it is often difficult to clear clotted cannulae because of the 180° bend as well as the 60° step, which interfere with the passage of a declotting catheter. The insertion of these cannulae requires careful judgement if the loop and the step are to lie in the appropriate position for alignment of the Teflon vessel tip in the cannulated vessel. Ramirez, Swartz, Onesti, Mailloux, and Brest (1966) described a "winged in-line" cannula which overcame the difficulty in declotting. We have developed a modification of this cannula, which has been in use in the East Birmingham

made in each wing, and the proximal portion of the cannula projects 5 cm. ahead of the wing.

METHOD OF INSERTION

The vessel is exposed for cannulation. A space distal to this site just large enough for the wing is made between two tissue layers (usually beneath the deep fascia, or between muscles), while the distal part of the cannula is passed along the same tissue plane and out through an oblique stab incision at a suitable site. Care is taken to ensure that the cannula lies in line with the vessel to be cannulated. The holes in the wing can be used for suturing the wing to the deep fascia if desired; this may be useful in confused and violent patients, but is probably undesirable if it is intended that cannulae should remain in situ for more than a few weeks.

The proximal portion of the cannula is normally trimmed to within 0.5 to 1 cm. of the wing. A Teflon vessel tip of appropriate size is then inserted, a fine silk suture is passed through the vessel wall to anchor the intima, and the vessel is cannulated in the usual way, one proximal and two distal ligatures round vessel and cannula normally being used. If recannulation of the same vessel is required on a later occasion, a similar cannula is used, but is trimmed to leave a longer portion ahead of the wing; it is then possible to use the same track as before.

Book Reviews

Documentation from Cradle to Grave

Medical Record Linkage. By E. D. Acheson, M.A., D.M.(Oxon.), M.R.C.P.(London). (Pp. 213+xviii; illustrated. 25s.) Published for the Nuffield Provincial Hospitals Trust by Oxford University Press, London, 1967.

Nowadays, as we travel from birth to death, we leave behind us a vast accumulation of personal information about our changing health and social circumstances. This information is recorded in separate places and at different times in the files of dozens of different medical and social agencies. A national system for piecing together the more important and reliable fragments of this scattered medical and social information in a series of personal, cumulative files would undoubtedly advance our knowledge about the aetiology and progression of many

diseases. The revolution in data-processing techniques that has taken place since the war has removed one major obstacle in the way of achieving such a national system of medical record linkage, but there remains the formidable problem of how to standardize the recording of the information and how to gather it in from its widely scattered sources.

Dr. Acheson, Reader in Medicine at Oxford University and director of the Oxford Record Linkage Study, is a pioneer in this field—so important to the future of epidemiological

research. He has convincingly demonstrated that routine record linkage is feasible at the regional level, and his experiment has already yielded research dividends in a series of papers in scientific journals. In this important book he traces the historical origins of our ideas about record linkage, gives a detailed technical account of the Oxford experiment, and makes sensible and practical suggestions about how a national scheme might be introduced. On the way he discusses the issues of breach of medical confidence, possible abuse by the State, and the general distrust in Britain of national registration, with its echoes of wartime restrictions, Buchenwald horrors, and Orwell's 1984.

C. R. LOWE.

Shock

Diagnosis and Treatment of Shock. By Max Harry Weil, A.B., M.D., Ph.D., F.A.C.P., and Herbert Shubin, A.B., M.D., F.A.C.P. (Pp. 391+xxvii; illustrated. 96s.) Edinburgh: E. & S. Livingstone. 1967.

This comprehensive book on shock has benefited greatly from the new emphasis in America during the last five years upon clinical rather than animal studies. It combines the mature views of many leading authorities with the recent experience of the Shock Research Unit at Los Angeles County General Hospital, where there is a wealth of clinical material. The classical sequence of pathophysiology, diagnosis, and treatment is adopted and the links between these stages can be much more securely based now that the guesswork between what is true of the dog and what of man has been largely eliminated.

A very strong team of authors, for instance M. I. Gregersen on volume relations, E. C. Bradley on haemo-dynamic aspects, and S. M. Levenson on metabolic changes, makes the section on pathophysiology particularly impressive. In the diagnostic section a variety of types of shock is distinguished. Among these, those due to blood loss, fluid loss, and infection are classical. Shock due to myocardial infarction, vascular obstruction, hypersensitivity, anaesthesia, and drugs are valuable additions to this section, but the inclusion of shock due to endocrine failure seems somewhat outside the usual scope. The section on treatment is based both on the research studies and on the practical lessons of a busy clinical department.

Throughout the book there is a wealth of diagrams and illustrations, many of them very clear and informative. Attention is drawn to a number of new studies—for instance, the value of comparisons between central and capillary haematocrits as an index of peripheral blood flow.

In considering the value of blood volume determinations, a good point is made that a convenient, rapid technique for estimation of fat-free body weight, and hence the expected

normal volume, would be more helpful than further improvements in blood volume estimation. However, no mention is made of the improved estimates of the expected normal blood volume which can be obtained by combining knowledge of height and weight.

The new clinical details of the different types of shock largely derive from recent improvements in monitoring. Though several pitfalls and hazards of these techniques are pointed out, Dr. Weil looks forward to further advances whereby computer analysis will not only give continuous information on the state of the patient but will automatically make appropriate adjustments to treatment. Whether or not this is a true prophecy, the book is a good guide to what can be done now.

J. P. BULL.

Cellular Chemotherapeutic Problems

Experimental Chemotherapy. Vol. 4. Chemotherapy of Neoplastic Diseases. Part 1. Edited by R. J. Schnitzer and Frank Hawking. (Pp. 670+xxii. £10 16s.) New York and London: Academic Press. 1966.

This book is the fourth of a series of volumes on experimental chemotherapy, and the title is interpreted in its widest possible sense. Previously issued parts have been concerned with the agents used in protozoal, fungal, and bacterial infections, and about 200 pages of the present book are supplementary to the previous three volumes, expanding them and introducing the results of recent research. This is a most valuable service to owners of the previous volumes, and J. Hill's account of modern developments in the chemotherapy of malaria and Jillian M. Bond's chapter on antibiotics used in the chemotherapy of bacterial and fungal infections are of particular interest.

The main part of the book, however, is

composed of material and subjects quite new to the series. At first it was surprising to me to find cancer chemotherapy and the therapy of infections dealt with in the same book. On reflection, however, the logic of the editors in considering cellular chemotherapeutic problems as a whole emerges triumphantly. A short introductory chapter by L. A. Elson serves to focus the reader's attention on this unity of chemotherapy. V. M. Rosenoer very fully discusses the problems of drug evaluation and the special aspects of experimental design. The statistical treatment of data is well discussed and a very full bibliography of recent papers is included.

The next 300 pages are a *tour de force* by J. A. Stock, who gives a splendid account of the antimetabolites and the antitumour antibiotics. The content of his chapters is absolutely up to date and well documented. An exhaustive bibliography follows each of the two sections. Tumour inhibition, pharmacology, and metabolism of the drugs is described in detail, together with mechanisms of action, drug resistance, and clinical applications. It is a revelation of how well a mass of information can be analysed and presented. Many of the drugs which are described have been evaluated and found wanting in human clinical use. The cautious approach of Stock is emphasized in his comment on mitomycin, when he says "the discrepancy (between clinical and experimental results) provides a good illustration of the danger of a too eager extrapolation of results in the experimental animal."

The authors have done excellent justice to their subjects, and in this Anglo-American series the British reader may feel reflected pride in the literary and scientific performance of Elson, Rosenoer, and Stock, all of whom hail from the Chester Beatty Institute. This series has a place of great value in the medical libraries of the world and further volumes will be eagerly awaited. The book can be enthusiastically recommended both on its own and as part of a larger project.

P. S. BOULTER.

Disorders of the Heart and Circulation

Disorders of the Heart and Circulation. Symposium, Edinburgh, 1965. Royal College of Physicians of Edinburgh. (Pp. 162; illustrated. Paper 25s.) Edinburgh: Royal College of Physicians, 1966.

The good symposiast should really do his task twice over, first for the listener and then for the reader. Certain learned societies ordain that papers be spoken and not read, and if we are listeners we owe them a debt. But the transcribed tape-recording will then make hard reading, and the slide, so evocative in the lecture, is bleak and silent on the printed page. Two versions is the only answer.

The seven symposiasts convened by the Royal College of Physicians of Edinburgh took their task to heart and have set out their ideas in an engaging way in this little volume. Sir John McMichael's George Alexander Lecture "Some Observations on the Micro-circulation" is a neat summary of the Hammersmith work on the applied physiology of the small pulmonary blood vessels in mitral stenosis and the retinal changes in hypertension and diabetes. The surgical treatment of aortic valve disease from the viewpoint of the physician (Dr. R. W. D. Turner) and the surgeon (Mr. A. Logan) is fairly weighed up. The authors' anxieties and travails in the early days of cardiopulmonary bypass surgery will sound a sympathetic note in the breasts of many of their colleagues outside Edinburgh.

The cardiomyopathies find Professor J. F. Goodwin on a favourite theme. At best, the term is a diagnostic waste-paper basket. It has no more specificity than "infectious fever," but it is the best we can manage at present. Professor Goodwin popularized the designations "congestive," "constrictive," and "hypertrophic obstructive" which helped by distinguishing the three main groups. Each of them can mimic the clinical picture of well-known diseases of entirely different nature. For instance, constrictive cardiomyopathy and non-calcific constrictive pericarditis can defy differentiation by the most enlightened clinician. Yet the latter is curable and the other is not. Professor Goodwin's Sydney Watson Smith lecture, reproduced here in full, is the best available summary of the subject. Endomyocardial fibrosis (Dr. D. Emslie-Smith) and viral cardiomyopathy (Professor N. R. Grist) complete a useful survey of these mysterious conditions.

WALTER SOMERVILLE.

A Dermatopathologist's Lifetime

Dermatopathology. In two volumes. By Hamilton Montgomery, M.D. (Vol. 1: pp. 650+viii+index. Vol. 2: pp. 651-1247 +vi+index; illustrated. £24 set of two vols.) New York: Harper & Row, 1967.

Every doctor has at some time heard that dermatology is more art than science. Why has this idea persisted for so long? Perhaps because so many of its physical signs depend more on visual appreciation than on the other senses. Another reason has certainly been the inability of dermatologists and pathologists to apply the analytical methods of

other branches of medicine to the study of the skin. All analysis of skin disease must start with pathology, but medical students and trainee dermatologists are too often allowed to pass through their teachers' hands with but little knowledge of its histopathology.

At the Mayo Clinic students of dermatology have long been taught that their best friend is the microscope, and credit for this must largely go to Dr. Hamilton Montgomery and his pupils. His standard textbook with the late Dr. Ormsby on diseases of the skin is already in its ninth edition; he has now satisfied those who have long hoped that he would write a purely histological work as a companion to it. His *Dermatopathology* is large and covers about 1,300 pages in two volumes weighing ten pounds (4.5 kg.) and costing sixty dollars. It is written in his own personal style and appears in places to be almost autobiographical. One wonders how some phrases will read in five to ten years' time. "This is discussed further in the forthcoming 9th Edition of *Diseases of the Skin*, by H. Montgomery" (p. 383); "my colleague at the Mayo Clinic, S. A. Muller, is preparing a monograph on herpes simplex in all its aspects" (p. 531).

The arrangement of the book is conventional with preliminary chapters on definitions, biopsy, normal structure, and histochemistry (the latter two by R. K. Winklemann). Inevitably there will be some omissions, considered culpable by some readers, but books such as this are not intended to be encyclopaedic.

The very personal style with its free use of the first person singular may irritate, but the book is not really so egocentric. Other views than the author's are expressed and discussed. The references to cases shown on papers presented at various conferences and congresses and colleagues' slides sent to him make it more vivid and personal; it is, as it were, an account of a dermatopathologist's lifetime. For those who have met him, or admired his work, or lived through his time, this book will be intensely interesting. On almost every page one feels that the lines can only have been written by "Ham" Montgomery.

C. D. CALNAN.

Malnutrition in Primitive Countries

The Assessment of the Nutritional Status of the Community. By Derrick B. Jelliffe, M.D., F.R.C.P., F.A.P.H.A., F.R.S.H., F.A.A.P. (Pp. 271; illustrated. 30s.) Geneva: World Health Organization. London: H.M. Stationery Office, 1966.

The author of this useful book, who directs the Caribbean Nutrition Institute in Jamaica, has compiled his text in consultation with 25 of the world's leading nutritionists. Its purpose is to give guidance and practical advice to those responsible for the detection of signs of malnutrition, in all its various forms, in those parts of the world in which it occurs most frequently.

Its chapters cover: direct nutritional assessment of human groups, indirect nutritional assessment of human groups, assessment of ecological factors, nutrition surveys, and social problems in different groups. Subdivisions

of chapters deal with topics such as the clinical signs of malnutrition, nutritional anthropometry, biochemical tests, and biophysical methods. Perhaps its most important feature is its wealth of photographs—many in colour—of patients suffering from malnutrition, including close-ups of the outward parts of their body which are affected. Thus there are excellent photographs of the eyes in vitamin-A deficiency, of the gums in scurvy, and of the skin in pellagra. A photograph to illustrate ecological factors shows a group of Eskimo children sitting for a picnic meal on the kitchen floor, tended by their mother and entertained by an older brother strumming his guitar.

To aid the worker in the field, specimen forms are included, with spaces in which ticks can be placed against those signs of malnutrition present in the subject under examination. Details are given of the best ways of measuring heights, weights, arm circumferences, and skinfold thicknesses in children, and an annex tabulates standard values with which these measurements can be compared. Biochemical tests are recommended for assessments of the nutritional status in regard to protein, ascorbic acid, thiamine, riboflavin, niacin, iron, folates, and iodine. About 300 references to the literature are cited, and a good subject index is included.

A minor criticism is an occasional tendency to ascribe to modern workers findings made many years ago. Thus the discovery of the effect of acute infections in lowering vitamin A in the blood, ascribed to McLaren in 1966, was reported by Lindqvist in 1937, and has been frequently confirmed since then. But the purpose of the book is to help the worker in the field, and not to contribute to the history of nutrition. For those whom it is primarily intended it will be invaluable. Many others, however, will doubtless learn with interest and profit about the many practical problems to be faced in the assessment and correction of malnutrition.

T. MOORE.

Strike in Saskatchewan

'Doctors' Strike. Medical Care and Conflict in Saskatchewan. By Robin F. Badgley and Samuel Wolfe. (Pp. 201+xiii. \$6.50.) New York: Atherton Press, 1967.

Robin F. Badgley is a lecturer and specialist in public health administration. Samuel Wolfe, now the medical director of a group practice in Saskatoon, Saskatchewan, was a commissioner of Saskatchewan's medical care plan. These collaborators, by writing a lengthy account of previous medical and political squabbles in Saskatchewan and by dwelling on much detail in the conflict between the politicians and the doctors, have produced this book.

The Government's medical care plan caused the "strike" in 1962, but the doctors made emergency health services available. The dispute was largely settled through the wisdom and advice of Lord Taylor, who was sent by the British Government, on the invitation of the Prime Minister of Saskatchewan, to act as mediator. He succeeded in obtaining concessions from both sides, peace was made, and the "strike" ended. At the time it caused general interest, but it was less epoch-making than the authors would imply.

A summary is given of Britain's National Health Service and other health organizations now being considered in Canada and the United States. Much attention is paid to political direction of health services, but the doctor-patient relationship and medical ethics receive less attention in spite of their fundamental importance.

ARTHUR S. MACNALT. Y.

Human Behaviour

An Introduction to Psychopathology. 2nd edition. By D. Russell Davis, M.A., M.D., F.R.C.P., D.P.M. (Pp. 158+x. 16s.) London: Oxford University Press. 1966.

The first edition in 1957 was an expansion of the author's psychopathology lectures at Cambridge; now the text has been entirely rewritten to include more clinical and experimental findings at the expense of theoretical discussion. The result is a very clearly written, readable book. It was originally designed to tempt the experimental psychologist out of his laboratory and into the clinic, and at the same time to get the clinician thinking about possible psychosocial explanations of disturbed behaviour in his patients. While still fulfilling this function, it should also be of interest to anyone with a flexible mind who is interested in human behaviour.

The first chapters are devoted to various models which might help to generate useful hypotheses about abnormal behaviour. These include laboratory models such as the sensory deprivation situation, and naturally occurring models such as the reaction to earthquakes, bereavement, or brainwashing. One of the highlights is the description of the author's own well-known experiments with the Cambridge Cockpit. Presented with a machine which they could not make to work, under conditions of high drive, the subjects manifested a degree of psychopathology which is unusual in the laboratory situation.

Some became anxious, others aggressive; many became curiously inert or talked repetitively about details of the task; and a few went out drinking. It is surprising that this experimental design has not been used much in recent years; certainly the frustrations of real life are coming more and more to resemble the laboratory situation.

After a critical chapter on inheritance, the various mental disorders are discussed with particular reference to possible causative factors in the family and social environment. A full and varied section on the psychosocial causes of mental subnormality may be a surprise to some. Recent work on the families of schizophrenics is dealt with leniently, and the reader unfamiliar with the literature may get the impression that there is good evidence that the parents' behaviour plays a part in causing schizophrenia. Concerning disorders in adult life, the author writes "there is little systematic evidence on which to base a discussion of the psychosocial causes of mental illness. . . ." Nevertheless, the discussion ranges over possible factors such as widowhood, retirement, and the departure of children from the home. The final chapter on psychotherapy gives some idea of how the psychological models may be used in the planning of treatment.

The book makes no claim to comprehensiveness. Even so, in such a short space, many topics get only a brief mention; I would willingly have forgone the section on congenital malformations to learn more about the effect of separating mother and child shortly after birth. In his new department at Bristol University Professor Russell Davis is well placed and well qualified to apply the hypothetico-deductive method and experimental technique of psychology to the difficult problems of family pathology. There is certainly a great need for such a rigorous approach in this field of inquiry, and it is to be hoped that the book will encourage others, both psychologists and clinicians, to join him in the task.

N. R. GRIST.

Books Received

Review is not precluded by notice here of books recently received.

Dinamica Proceselor Cerebrale. By A. Kreindler. (Pp. 229. 16.50 Lei.) Bucarest: Editura Academiei Republicii Socialiste Romania. 1967.

Lehrbuch der Psychiatrie. By Professor Hans Heinrich Wieck. (Pp. 414+xvi. illustrated. DM. 44.) Stuttgart: F. K. Schattauer. 1967.

What is Allergy? A Guide for the Allergic Person. By Raymond T. Benack, M.D. (Pp. 158+xiii. \$6.75.) Springfield, Illinois: Charles C. Thomas. 1967.

Introduction to Dental Anatomy. 5th edition. By James Henderson Scott, D.Sc., M.D., F.F.D. R.C.S.I., and Norman Barrington Bray Symons, M.Sc., B.D.S., F.F.D. R.C.S.I. (Pp. 422+x; illustrated. 55s.) Edinburgh and London: E. & S. Livingstone. 1967.

The African Witch. With Particular Reference to Witchcraft Beliefs and Practice among the Shona of Rhodesia. By Michael Gelfand, C.B.E., M.D., F.R.C.P., D.P.H. (Pp. 227+xvi; illustrated. 30s.) Edinburgh and London: E. & S. Livingstone. 1967.

Clinical Virology. By R. H. A. Swain, M.A., M.D., F.R.C.P.Ed., F.C.Path., F.R.S.E., and T. C. Dodds, F.I.M.L.T., F.I.I.P., F.R.P.S. (Pp. 318+xii; illustrated. 75s.) Edinburgh and London: E. & S. Livingstone. 1967.

Venen-Fibel. 2nd edition. By Dr. F. Haid-Fischer and Dr. Helmut Haid. (Pp. 218+xv; illustrated. DM. 19.80.) Stuttgart: Georg Thieme. 1967.

Micro-Vascular Surgery. Report of First Conference, 1966. Mary Fletcher Hospital, Burlington, Vermont. Edited by R. M. Peardon Donaghy, M.D., and M. Gazi Yasargil, M.D. (Pp. 171+xii; illustrated. DM. 48.) Stuttgart: Georg Thieme. 1967.

Die Krankheiten der Schilddrüse. By K. Oberdisse and E. Klein. (Pp. 595+xv; illustrated. DM. 148.) Stuttgart: Georg Thieme. 1967.

The Mechanics of Healing. By Parnell Bradbury, D.O., M.R.O., M.B.N.O.A. (Pp. 141; illustrated. 37s. 6d.) London: Peter Owen. 1967.

Cerebrovascular Disorders. By James F. Toole, M.D., and Anel N. Patel, M.D. (Bombay), M.R.C.P.(Edin.). (Pp. 280+xv; illustrated. No price given.) New York: McGraw-Hill. 1967.

Viral Ecology

The Natural History of Viruses. By C. H. Andrewes. (Pp. 237+viii; illustrated. 55s.) London: Weidenfeld & Nicolson. 1967.

From the fluent pen of Sir Christopher Andrewes comes yet another highly readable, entertaining, and informative book. This one deals with viruses from a broad biological point of view, as organisms involved in the complex interactions of living things which form the stuff of ecology (which anthropocentric medical men so often treat as mere "epidemiology").

A general introduction to viruses and their interactions with metazoan and bacterial hosts is followed by the main section dealing with transmission of viruses. Examples are drawn freely from man, other animals and plants, from the jungles, the tundras, and Wiltshire. Representative chapter-headings are "Influenza, Ringer of Changes," "Mosquitoes, Herons, and Pigs," and "Boots, Worms, and Fungi."

The final section deals with more speculative aspects of ecology, such as latency, congenital infections, and tumours, and concludes with a brief consideration of the ways in which man might try to influence viral ecology for his own benefit.

The book is well illustrated and has useful appendices, bibliography, and a glossary. The latter, together with the lucid and entertaining style, makes this book suitable for the intelligent layman and general student of biology as well as for the undergraduate in medicine. All medical men interested in the interplay of living things should enjoy the stimulating ideas and up-to-date background information it provides for those concerned with communicable diseases at patient or community level. Virologists and those concerned in teaching virology will appreciate the broad approach and wealth of detail of this fascinating book.

Cancer in Pregnancy. By Larry McGowan, B.S., M.D. (Pp. 142+xi. \$7.50.) Springfield, Illinois: Charles C. Thomas. 1967.

The Rays are not Coloured. Essays on the Science of Vision and Colour. By W. D. Wright, A.R.C.S., D.Sc. (Pp. 154+x. 35s.) London: Adam Hilger. 1967.

Salisbury 200. The Bicentenary of Salisbury Infirmary. 1766-1966. By Members of the Hospital Staff. (Pp. 162; illustrated. 12s. 6d.) Salisbury: Salisbury General Hospital. 1967.

"Instinct and Intelligence." The Science of Behaviour in Animals and Man. By S. A. Barnett. (Pp. 250+xiii; illustrated. 45s.) London: MacGibbon & Kee. 1967.

Ausgewählte Internationale Bibliographie. 1952-1963. Zur Verkehrsmedizin. By Hermann Hoffmann. (Pp. 192. No price given.) Munich: J. F. Lehmanns. 1967.

Speech Handicapped School Children. 3rd edition. Edited by Wendell Johnson and Dorothy Moeller. (Pp. 562+xiv. No price given.) New York: Harper & Row. 1967.

Marvels of Medical Engineering. By Norman Carlisle and Jon Carlisle. (Pp. 144; illustrated. 27s. 6d.) London: Oak Tree Press. 1967.

CONFERENCES AND MEETINGS

Chemotherapy of Tuberculosis in Developing Countries

[FROM A SPECIAL CORRESPONDENT]

A symposium on the chemotherapy of tuberculosis in developing countries was held at the Royal College of Surgeons of England on 25, 26, and 27 September.

Economics of Tuberculosis Control

With Dr. WALLACE FOX (London) in the chair, the first session began with a paper by Dr. H. T. WAALER (Oslo) on the economics of tuberculosis control, which was read in his absence. He emphasized the need to allocate resources to produce the maximum reduction of a disease problem per unit of expenditure. This principle applied at every level, from the Government to the director of health services, the tuberculosis services, and the individual clinician. At some levels there was a choice in allocating resources to one disease or another; at other levels a choice between approaches to the actual disease had to be made. Dr. L. MOKHTARI (Algiers) reported that 92% of the budget on tuberculosis in Algeria was spent on sanatorium beds, 7% on the clinic services, and 1% on B.C.G. vaccination. It was current policy to reduce the number of beds from 7,000 to approximately 5,500 to permit expansion of the other sectors. Dr. P. W. KANT (Nairobi) said that in East Africa there was a striking gap between the 80% or more cure rates achieved in the treatment of patients in controlled clinical trials and the 50% achieved by the general tuberculosis services in the same area. He favoured concentrating therapy exclusively on the effective use of standard drugs rather than dissipating resources on failure patients. He advocated diagnosis by smear and culture examination in patients producing sputum, and B.C.G. vaccination on school entry. Dr. K. M. CARRON (London) summarized the currently available regimens and their cost, recommending one year of treatment as the first priority, and the use either of thiacetazone plus isoniazid, if possible with an initial streptomycin supplement, or twice-weekly intermittent streptomycin plus high-dosage isoniazid. Dr. F. POLANSKY (Prague) reported that in the central Bohemian region over the five-year period 1958 to 1962 the expenditure on the tuberculosis outpatient facilities was 25% of that on hospitals and sanatoria. The total expenditure on 6,500 patients who were being treated for active tuberculosis on an outpatient basis was less than the expenditure on a sanatorium with 325 beds. Mr. D. E. SEYMOUR (Welwyn Garden City) reminded the audience of the formidable expenditure involved in testing new drugs. The cost to prepare a new drug for clinical trial was rarely as low as £100,000.

Drug Trials

At the second session, chaired by Dr. J. R. BIGNALL (London), Dr. J. FRIMODT-MÖLLER (South India) reported on a chemotherapy project in six small towns in India, in three of which the patients were treated with isoniazid and in three with isoniazid plus P.A.S. At the end of one year 45% of the patients who were initially smear positive had become culture negative, as had 63% of those initially smear negative but culture positive. There was a marginally higher prevalence of drug resistance in the study population at the end of the survey than at its start. Dr. J. F. HEFFERNAN (London) summarized the results of the series of East African/British Medical Research Council controlled clinical trials, which had established thiacetazone 150 mg. plus isoniazid 300 mg. in a single tablet as a standard regimen in East Africa, supplemented initially, when possible, by two months of daily streptomycin. Dr. D. H. SHENNAN (Newcastle) reported the results of a controlled trial in Rhodesia which demonstrated that thiacetazone plus isoniazid was as effective as streptomycin plus P.A.S., 76% of 58 patients compared with 84% of 55 being culture negative at six months; streptomycin plus thiacetazone was substantially inferior, for only 46% of 58 patients were culture negative. Dr. N. K. MENON (Madras) summarized a trial in Madras. In South Indian patients thiacetazone plus isoniazid was therapeutically as effective as P.A.S. plus isoniazid, but rather more toxic. Dr. P. A. L. HORSFALL (Hong Kong) reported the results of a controlled trial which showed that thiacetazone plus isoniazid in the Chinese in Hong Kong was somewhat less effective than P.A.S. plus isoniazid in terms of culture negativity at one year and the emergence of isoniazid resistance.

Drug Resistance

At the third session on thiacetazone sensitivity and resistance, chaired by Dr. N. RISØ (Paris), the chairman reminded the audience that pretreatment strains of tubercle bacilli type W and H37Rv behaved differently from strains from patients with acquired thiacetazone resistance in Europe and North Africa, whereas in South India the behaviour of many pretreatment strains resembled European strains with acquired resistance. Dr. D. A. MITCHISON (London) described differences between the pretreatment thiacetazone sensitivity of strains in different parts of the world. In East Africa and Madras a substantial proportion of strains were thiacetazone-resistant, associated with low virulence and susceptibility to hydrogen peroxide. In Hong Kong there was often

thiacetazone resistance with full virulence. He reviewed animal studies which showed that the decreased pretreatment thiacetazone sensitivity influenced the response to treatment with thiacetazone. He discussed anomalies in the differences in the response to treatment with thiacetazone plus isoniazid from one area to another, for the regimen was effective in East Africa and India, but less so in Hong Kong. A lively discussion ensued on whether or not a laboratory finding of natural resistance resulted in a failure of clinical response to thiacetazone-containing regimens.

Dr. J. GROSSET (Algiers) had found that pretreatment Algerian strains resembled British strains in being fully sensitive to thiacetazone, unlike strains from Hong Kong and Madras, and that the sensitivity to ethionamide was the same in all four groups of strains. He further reported that there was some correlation between acquired resistance to ethionamide and thiacetazone, but not true cross resistance. Dr. P. R. J. GANGADHARAM (Madras) had studied the pretreatment thiacetazone sensitivity of Indian tubercle bacilli in a survey in 10 large cities in India. There were differences from centre to centre, the northernmost city (Amritsar) having strains as sensitive as those from Britain, the sensitivity progressively decreasing until Madras, the most southern city, which had the most highly resistant strains.

Drug Toxicity

At the fourth session, with Dr. J. PEPYS (London) in the chair, thiacetazone toxicity was discussed. Dr. A. B. MILLER (London), in a general review, summarized the early experience which led to the abandonment of thiacetazone in the early 1950s. Its safety in combination with isoniazid was established in a series of controlled trials in East Africa. Subsequently, widely divergent reports on toxicity from different parts of the world led to a co-operative blind investigation by the Medical Research Council into the incidence of thiacetazone side-effects in 14 countries. This suggested there were genuine differences between countries, Czechoslovakia, Hong Kong, and Pakistan having the highest levels, Cyprus and India the lowest. The differences might be due to racial, dietary, or climatic factors or differences in observing and reporting side-effects. A second study was investigating these factors further, and also the claims of benefits from vitamin and antihistamine additives. The world literature suggested that jaundice was not more common in regimens containing thiacetazone 150 mg. than in control regimens, but there was evidence that the increase in haemoglobin,

which normally occurs during treatment, was less in patients on thiacetazone-containing regimens. The incidence of cutaneous hypersensitivity was very variable, and in some areas exfoliative dermatitis was encountered. There was evidence that thiacetazone could potentiate streptomycin toxicity. Sister M. AQUINAS (Hong Kong) reported a high incidence of side-effects with thiacetazone plus isoniazid in a study in Hong Kong, particularly cutaneous and haematological. Although 37% of 150 patients had rashes, about half generalized and some with stomatitis or a purpuric element, there had been no case of exfoliative dermatitis. The haemoglobin fell on average from 11.9 g./100 ml. pretreatment to 11.5 g./100 ml. at a year, in contrast to a rise from 11.9 to 13.3 g./100 ml. in the control group on P.A.S. plus isoniazid.

Dr. H. RADENAC (Morocco) summarized differences observed in toxicity in four centres in Morocco to thiacetazone plus isoniazid. In Rabat toxicity, notably cutaneous hypersensitivity, was common, whereas side-effects were very uncommon in Marrakesh and were intermediate in frequency in Meknes and Tangier. Women had more toxicity than men. Finally, Mr. K. TATTERSALL (London) reported on a laboratory evaluation of the antituberculous activity of thiacetazone and ethionamide.

Experimental Study of Intermittent Regimens

In session five, under the chairmanship of Dr. D. A. MITCHISON (London), the experimental basis of intermittent regimens was discussed. Dr. J. M. DICKINSON (London) described an in-vitro technique for exposing cultures of tubercle bacilli to chemotherapeutic agents for differing periods of time and studying the influence of such exposure on the growth of the cultures. Streptomycin could be expected to be highly effective when used in intermittent regimens, followed by ethionamide, isoniazid, and ethambutol. Pyrazinamide and cycloserine were in a doubtful category, thiacetazone and thiocarlide were unlikely to be useful, and P.A.S. gave variable results. She also reported in-vivo findings in the guinea-pig, which she considered a particularly good model for man, provided note was taken of species differences in drug metabolism. Dr. J. C. BATTEN (London) reported experiments with streptomycin plus isoniazid in murine tuberculosis. Both streptomycin and isoniazid were effective intermittently, but as the interval between doses increased the streptomycin effect was maintained but isoniazid was impaired. He pointed out that isoniazid is particularly rapidly excreted in mice.

Dr. G. CANETTI (Paris) described his mouse model, emphasizing that treatment was started after two weeks' delay when 10^4 bacilli were present, so that in effect the situation resembled a medium-sized cavity. Only certain drugs could be studied in mice, which were not suitable for cycloserine, P.A.S., and thiacetazone. It was important to use a murine strain which was highly susceptible, young animals, a highly virulent

bacillary strain, and a standardized inoculum. The three important factors in the response were the frequency of administration of drug, the dose, and the duration of an initial period of daily chemotherapy. Bacillary resistance was frequent in long-term intermittent chemotherapy, especially if the residual population exceeded 400 viable units. The mouse was an excellent model but unsatisfactory for studying relapse, since organisms almost invariably grew out after stopping chemotherapy, and, also, reversion from resistance towards sensitivity both with streptomycin and isoniazid commonly occurred.

Clinical Aspects of Intermittent Regimens

The sixth session, with Professor J. G. SCADDING (London) in the chair, considered clinical aspects of intermittent regimens. Dr. N. K. MENON (Madras) reported a comparison of streptomycin 1 g. plus isoniazid 14 mg./kg. body weight twice weekly (S.H.T.W. regimen) with the same combination once weekly (S.H.O.W. regimen). The S.H.T.W. regimen achieved quiescence in 92% of patients at a year compared with 71% on the S.H.O.W. regimen, a highly significant difference. The S.H.T.W. regimen was uninfluenced by the inactivation rate of isoniazid or the dosage of streptomycin (1 g. or 0.75 g., which had also been allocated at random). In the S.H.O.W. regimen 82% of the slow compared with 60% of the rapid inactivators had quiescent disease—a significant difference, but there was a smaller difference between the two streptomycin dosages. In a second phase two further regimens were added, making a four-regimen concurrent comparison. In one regimen (S.H.Z.O.W.), pyrazinamide 90 mg./kg. was added to the once-weekly streptomycin plus isoniazid, and in the other (S.H./S.H.O.W.) the once-weekly 2-drug combination was preceded by one month of daily streptomycin plus isoniazid. At one year quiescent disease was achieved in 95% of the S.H.T.W. patients, 88% of the S.H./S.H.O.W. patients, 75% of the S.H.Z.O.W. patients, and 66% of the S.H.O.W. patients. Although the S.H./S.H.O.W. regimen achieved a high level of success, there was evidence that it, like the two once-weekly regimens, was affected by the inactivation rate of isoniazid. Only the twice-weekly regimen was really robust. Dr. S. P. TRIPATHY (Madras) reported on the bacteriological findings from the same study, which showed that the emergence of isoniazid and streptomycin resistance in the four regimens approximately paralleled their efficacy, and that in the S.H.O.W. regimen the isoniazid was inadequate in the rapid inactivators and the streptomycin was inadequate in the low-dosage streptomycin group. Adding the third drug, pyrazinamide, in the S.H.Z.O.W. regimen made up for the streptomycin deficiency in the low-dosage streptomycin group but not for the isoniazid inadequacy. The addition of the initial intensive phase of chemotherapy in the S.H./S.H.O.W. regimen corrected the deficiency of streptomycin in the low-dosage streptomycin group.

Dr. P. CHAULET (Algiers) reported the use of streptomycin plus high-dosage isoniazid twice weekly in 135 patients in Algiers, in 26 from the start of treatment, in 41 after one month, in 36 after two months, and in 32 after three or more months daily chemotherapy. All four regimens achieved a high level of success; overall 95% had quiescent disease at 12 months. In contrast, Dr. F. J. M. BURZONI (Morocco) reported unsatisfactory results with streptomycin 1 g. plus isoniazid 750 mg. combined in a large single intramuscular injection twice a week. The study was uncontrolled and the losses were high, but of 64 patients remaining for analysis 29 were classified as failures of chemotherapy. There was no obvious explanation for these findings which did not fit either the experimental or the other clinical reports. Dr. P. STRADLING (London) had satisfactory results with supervised continuation chemotherapy with streptomycin 1 g. plus isoniazid 650 mg. three times a week after an initial three months of standard triple daily chemotherapy. Of 139 patients 88% completed one year and 80% the planned 18 months. There was only one failure.

In the seventh session, under the chairmanship of Dr. R. GOULDING (London), the quality control of drugs for tuberculosis was discussed. Professor A. H. BECKETT (London) gave a general survey of what quality control entailed. Dr. H. STOTT (London) reported the striking deterioration of tablets and capsules of cycloserine in Madras. A current batch of 250-mg. tablets was found on assay to have a mean cycloserine content of 76 mg. at the time of issue to patients. Investigation showed that in the high tropical temperatures the humidity was particularly dangerous and that tablets dispensed in paper envelopes and kept in the patients' homes rapidly had less than the lower *British Pharmacopoeia* limit—within a matter of days—namely, in one experiment an average content of 41 mg. at 10 days and in another 21 mg. at 56 days. Dr. Stott emphasized the importance of care, not only in the manufacture, packaging, and in transit, but in storage in the tropics and dispensing for outpatients. Routine checks for potency were also necessary. Mr. Y. RICE (Basingstoke) discussed the quality control of cycloserine, Mr. T. E. V. HORSLEY (Ulverston) of streptomycin, and Mr. B. W. MITCHELL (Gilston Park) of P.A.S.

Laboratory Methods

In the last session of the symposium a discussion was held under the chairmanship of Professor J. W. CROFTON (Edinburgh) on the role of the laboratory in the chemotherapy of tuberculosis in developing countries. The panel members agreed in principle that simple methods were essential, but disagreed widely on the frequency with which smears, cultures, or sensitivity tests should be performed, and in which patients. Radiography was agreed to be less valuable than bacteriology, especially during treatment.

The symposium was sponsored by Smith and Nephew Associated Companies Ltd.

European Views on Liver Disease

[FROM A SPECIAL CORRESPONDENT]

The second meeting of the European Association for the Study of the Liver was held at Gothenburg, Sweden, on 22-24 September under the presidency of Professor Sheila Sherlock and with Professor S. Bengmark acting as local secretary.

Treatment of Infectious Hepatitis

Dr. U. P. HAEMMERLI (Zurich) reported an analysis of 471 consecutive admissions with acute infectious hepatitis to two public hospitals in Zurich. In one hospital the patients were treated routinely with corticosteroids, in the other they were not. Corticosteroid therapy lowered the serum bilirubin and transaminase levels but did not shorten the period of hospitalization. The mortality was 2.4% in the group treated with corticosteroids, due to ulcer complications, as compared with 0.7% in the untreated group. There was also an increased incidence of relapse after discharge from hospital in those given corticosteroids.

Dr. G. TYTGAT (Louvain) reported generally unfavourable results from the use of exchange transfusion in hepatic coma due to acute infectious hepatitis. This was also the experience of Professor Sherlock (London) and Dr. J. P. Benhamou (Clichy). Dr. R. FRISSIG (Berne) reported recent experimental studies in dogs with canine hepatitis, in whom the survival rate had been improved by exchange transfusion. Hyperimmune serum given intravenously had also been effective, and he and his colleagues had started a controlled trial on the use of gammaglobulin in severe hepatitis.

Dr. B. HARVALD (Copenhagen) reported the latest results of the Copenhagen controlled study of long-term prednisone therapy for cirrhosis. This trial had been initiated in 21% of 122 first-degree relatives of 42 histologically verified cases. Prednisone produced a temporary symptomatic and biochemical improvement, but to date had not improved the overall survival rate. A beneficial effect on survival might, said Dr. Harvald, be found in females with active non-alcoholic cirrhosis and high gamma-globulin levels, though the difference in survival was as yet of borderline statistical significance.

Dr. D. MÜTING (Homburg/Saar) gave an account of studies of the long-term effect of lactulose and *Bacterium bifidum* on protein metabolism in 27 patients with chronic liver disease. In a number of these tolerance had been improved to food protein, and blood ammonia level, the free serum amino-acids, and the free serum phenols had been reduced to normal. In the subsequent discussion Dr. J. P. HAEMMERLI (Zurich) stressed the importance of titrating the dose of lactulose

according to the response of the patient. Initially 20 g. daily should be tried, this being increased to 30-40 g. daily given in divided doses. The pH of the stools should be kept below 6.

Bilirubin Metabolism

Dr. A. BAKKEN (Oslo) opened a discussion on bilirubin metabolism. He had found that erythroblastotic infants had conjugated bilirubin in their sera at birth if their mothers had been heavily immunized during pregnancy. He postulated that the maternal bilirubin induces bilirubin glucuronyl transferase activity in the foetal liver, and this had been confirmed experimentally in rats. Dr. V. DESMET (Louvain) had studied the distribution of conjugated and unconjugated bilirubin in the liver in different varieties of cholestasis using selective histochemical stains. He had found that the bilirubin in bile thrombi was predominantly conjugated, whereas pigment accumulation in the cells was partly of the conjugated and partly of the unconjugated type. The presence of the latter might be due to deconjugation of conjugated bilirubin by β -glucuronidase, suggested Dr. Desmet. The concentration of this lysosomal enzyme had been shown to be increased in cholestatic jaundice.

Dr. G. ACOCCELLA (Milan) produced further evidence in favour of deconjugation of conjugated bilirubin in the liver. He had studied the distribution of bilirubin administered in conjugated form to Gunn rats after ligation of their bile ducts. Serum levels of unconjugated bilirubin rose, and this, together with the finding of an increased β -glucuronidase activity in the liver, suggested that the conjugated bilirubin was being deconjugated in the liver.

Dr. B. H. BILLING (London) reported that she had found a raised serum bilirubin level in 21% of 122 first-degree relatives of 42 patients with Gilbert's syndrome (idiopathic unconjugated hyperbilirubinaemia). She concluded that the disorder was inherited as an autosomal dominant with incomplete penetrance. Of interest was the considerable variation in serum bilirubin levels found in the probands. In 33% the serum bilirubin level had been on one occasion within the normal range.

A new syndrome of hereditary recurrent cholestasis was described by Dr. O. AAGENAES (Oslo). He had studied 16 patients, all related, with this condition. The patients had varying degrees of cholestatic jaundice from birth to between 1 and 6 years of age. After the cholestatic period development had been satisfactory apart from a tendency to leg oedema; but later cholestatic episodes recurred. Liver biopsy during the attacks showed a giant cell hepatitis. Seven of the patients had died in infancy of bleed-

ing, so early recognition of the disease permitting treatment with vitamin K was important.

Dr. A. SCOTT (London) drew attention to "the stagnant bile syndrome." The presence of bacteria in large numbers in the bile in patients with partial biliary obstructions and cholangitis leads to bacterial overgrowth in the small intestine with suboptimal B_{12} absorption and other features which mimic the intestinal "blind loop syndrome."

Iron Metabolism

Dr. M. BARRY (London) reported that he had found that desferrioxamine and diethylenetriamine penta-acetic acid differed in their relative affinities for the various chelatable iron pools in the body. Increased desferrioxamine chelatable iron did not necessarily indicate an increased total body iron; high values were found, for instance, in cholestatic jaundice. Dr. V. HOENIG (Prague) said that the administration of ethanol caused increased absorption of iron from a bivalent iron salt in cirrhotic patients but not in normal subjects. This effect could be prevented by simultaneous administration of pancreatin and to a lesser extent by intravenous pancreozymin.

Dr. R. WILLIAMS (London) described the clinical features of the specific arthropathy of idiopathic haemochromatosis. This had been present in 16 of 32 patients examined. Radiographs showed chondrocalcinosis due to deposition of calcium pyrophosphate, which was also responsible for acute episodes of crystal synovitis. Increasing age of the patient and duration of iron overload were important factors in the pathogenesis.

Pancreatic Disorders

Dr. G. A. MARTINI (Marburg/Lahn), using the pancreozymin secretin test, had found abnormal pancreatic function in more than half of 70 patients with proved chronic liver disease. Abnormalities were found as frequently in cryptogenic cirrhosis and active chronic hepatitis as in alcoholic cirrhosis. The characteristic high volume low bicarbonate concentration juice seen in haemochromatosis was also found in some patients with cirrhosis. Dr. W. CREUTZFELDT (Göttingen), in discussing the cause of the increased incidence of diabetes in cirrhosis (12-14%), reported further studies showing elevated plasma insulin levels in the fasting state, after glucose loading, and after intravenous tolbutamide in patients with cirrhosis. These findings were consistent with endogenous insulin antagonism as the most important factor in the impaired carbohydrate tolerance.

Psychotropic Drugs

SIR,—The letter of Dr. P. Leyburn and others (14 October, p. 108) is misleading enough to require answering, since it both ignores and oversimplifies the problems facing psychiatrists today.

The term depression is open to misunderstanding. It is employed in different ways, and there is no one accepted classification or terminology. Depressive illness is probably not a single entity. Clinically there are several recognizably distinct forms, responding differently to different treatments.

The M.R.C. trial was a valuable one. It was carried out on patients suffering from what traditionally would be called endogenous depression, with symptoms of self-depreciation with a morbid sense, sleep disturbance, hypochondriasis, retardation of thought and action, and agitated behaviour. These are patients of the type likely to respond to E.C.T., and known since 1960 to respond to tricyclic antidepressants such as imipramine. Early on in our investigations of the actions of antidepressant drugs we recognized that patients with endogenous depression would not generally respond to monoamine oxidase inhibitors, and could indeed be made worse by them. The M.R.C. trial therefore confirmed these early findings.

The monoamine oxidase inhibitors are particularly useful in cases of reactive depression. Here phobic anxiety symptoms are sometimes prominent, and the clinical picture often resembles that of anxiety hysteria. In other patients tiredness and lack of energy are the main complaints, similar to what in the past was called "neurasthenia." Somatic symptoms are apt to arise and become a focus on to which the patient's anxiety is displaced. Vicious circles of this type were difficult to break before the advent of the monoamine oxidase inhibitors, and no amount of investigation and reassurance would convince the patient that he was not afflicted by some fatal illness. A similar vicious circle may arise during or following a somatic illness, when anxiety and depression will perpetuate symptoms. It is this type of patient, so common in general practice and general hospital out-patients departments, who responds so well to the monoamine oxidase inhibitors. To confuse these patients with those with endogenous depression who require admission to a mental hospital is only adding confusion to an already confused subject. Dr. Leyburn and his colleagues write that there are many clinicians who have become doubtful of the value of monoamine oxidase inhibitors. I know of no physician or psychiatrist, dealing frequently with reactively depressed patients described above, who has become "doubtful of their value." That these drugs need to be given skilfully and discriminatingly goes without saying, but when used properly their value is considerable.

By all means let us have controlled clinical trials, but Dr. Leyburn and his colleagues can surely have little idea of the practical difficulties and time involved if they can write that "they should have little difficulty in carrying out a properly controlled trial to demonstrate this" (the value of monoamine oxidase inhibitors in psychosomatic conditions). The psychiatric departments of general hospitals today are already over-stretched in their commitments. If the M.R.C., or some other organization, will provide money for research units to be attached to psychiatric departments, then the controlled trials and proof for which Dr. Leyburn and his colleagues ask will be forthcoming.—I am, etc.,

P. DALLY.

Department of Psychological Medicine,
Westminster Hospital,
London S.W.1.

SIR,—In the point of view expressed by a Morpeth group of psychiatrists (14 October, p. 108) regarding Dr. William Sargent's advocacy of certain drugs in psychosomatic illness (30 September, p. 861) perhaps the reason for the variable results obtained in different parts of the country lies not so much in either the symptoms or the drugs but in the patients' constitutions, which have developed in response to differing climatic and social variants.

I recall a Scottish psychiatrist who observed that sodium amytal gr. 6 (0.4 g.) produced only a mild sedative effect in certain of his Edinburgh patients, but his similar patients in Northumberland just went to sleep on that dosage.

Psychosomatic (or preferably somato-psychic) patients are very sensitive. The lady quoted as eventually dying after eating cheese while taking iproniazid may on that occasion have had some other unnoticed or unknown factor which had a catalytic or cumulative terminal effect.

Similarly, patients who fall ill in climates or circumstances different from those in which they spent their earlier years may show an unexpected response to drugs which have been found satisfactory in the native community.—I am, etc.,

Bristol

G. M. LANGHAM-HOBART.

Future of the Regional Hospitals

SIR,—The National Health Service has much to be proud of in the improvement that has been achieved in the vast majority of regional hospitals. The future of these hospitals, whether old or new, however, is open to grave misgivings unless staffing and facilities within them is not a good deal more imaginative than is provided at present.

Public interest and money is being spent on building new hospitals, equipping intensive care units, coronary care units, renal units, etc., but unless they are properly staffed, not only by senior staff but with appropriate assistants, with accommodation for doing the work necessary to keep their departments really alive, they will never be first-class. At present little or no accommodation for discussion in departments is provided. Junior medical staff and secretarial help is kept at a minimum, no official link is made with teaching schools in the region, and senior staff are bogged down by overwhelming routine.

Much emphasis is laid on study leave for all grades of staff, but, important though this may be, attending courses is no substitute for an active department with a spirit of inquiry at the hospital in which the doctor works, whether he is senior or junior, and no teaching is as useful as the bedside teaching and informal discussion in a room attached to the department.

The number and seniority of junior medical staff in a department should not depend on numbers of beds but on what work should be done in the department. Difficulty in obtaining junior staff is put forward as a reason for not having them, but keen junior staff can always be obtained for a really active hospital, and hospitals that are static do not deserve any better help.

It is probably no fault of regional boards or management committees that they cannot provide what is necessary to keep our hospitals as proper medical centres, and senior staff from getting frustrated, as they are tied by finance and the decisions of committees. Could not the Ministry of Health take positive steps to combine the resources of our teaching schools with our regional hospitals, and set up joint medical committees from both, to arrange that their teaching and research work shall be complementary to each other?

Many of the senior medical staff of teaching schools and regional hospitals have for a long time recognized this situation, and in many cases there is such good will between them that semi-private arrangements for interchange of junior medical staff and sometimes medical students has been arranged at their instigation, albeit with the somewhat reluctant approval of their official governing bodies. The time has now come for such arrangements as these to be part of the normal programme which the National Health Service as a whole should recognize. Furthermore, some recognition to the staff of regional hospitals who assist with teaching would not come amiss, as they give a lot of extra time for the benefit of both those they teach and to maintaining a high standard in the hospitals. Unless the universities, the Ministry of Health, boards of governors and regional boards can produce some scheme to accomplish this the regional hospitals are likely to become second-class, and the junior staff and students at the teaching schools are in danger of losing a lot that would help them have a wider training.—I am, etc.,

Hitchin, Herts.

P. J. W. MILLS.

Pyloric Stenosis in Turner's Syndrome

SIR,—The prevalence of congenital hypertrophic stenosis in the general population is estimated to be about 2 to 5 per 1,000 live births,^{1,2} and Carter was able to demonstrate that the sex ratio for this malformation amounted to 5:1, boys being more affected than girls.³ Benson and King have drawn attention to a possibly high prevalence of this condition in patients with Turner's syndrome.⁴ We have investigated a series of 43 patients with Turner's syndrome and found two patients with congenital pyloric stenosis.⁵

The diagnosis of Turner's syndrome in Case 1 was established at the age of 19 years on the following criteria:

- (1) Sexual infantilism with primary amenorrhoea, infantile external and internal genitalia, and absence of breast development.
- (2) Dwarfism: height 143 cm.
- (3) Extragonadal malformations: short neck without webbing, low implanted and malformed ears, scoliosis, clinodactyly, striking brachymetacarpism of the fourth and fifth fingers of the right hand, and of the fourth finger of the left hand, oedema of the fingers and feet, hypoplastic nails, hallux valgus, shortening of the first metatarsal, and multiple pigmented naevi.
- (4) The sex chromatin was found to be negative in the buccal smear, and the karyotype in the peripheral blood was 45-XO.

The patient was the youngest of a family of four children, and weighed 2.65 kg. at birth after a pregnancy lasting 38 weeks. Persistent vomiting started seven weeks after birth. No information could be obtained about gastric peristalsis or a palpable gastric tumour, but the diagnosis was radiologically confirmed. Surgical intervention was proposed, but refused by the parents. Conservative treatment, however, was successful, and the vomiting stopped by the age of 7 months.

The diagnosis of Turner's syndrome in Case 2 was established at the age of 12 years on account of:

- (1) Dwarfism: height 128 cm.
- (2) Extra-gonadal malformations: short neck with webbing and low hairline, low implanted and malformed ears, hypoplastic and retrognathic jaw, shield-shaped chest with widely spaced nipples, clinodactyly, oedema of both fingers and feet, and multiple pigmented naevi.
- (3) The sex chromatin in the buccal smear was negative and the karyotype in the peripheral blood was 45-XO.

The patient was the first-born of a family of two children, and the duration of the gestation was probably 44 weeks. The birth weight was 3.5 kg. Between the fourth and eighth week of pregnancy unsuccessful attempts to procure a miscarriage with drugs were made. Persistent vomiting started from the first week after birth. Gastric peristalsis and tumour were noted, and the diagnosis was radiologically confirmed. Conservative treatment was successful, and the vomiting stopped at the age of approximately 6 months, at which time the child weighed 3.3 kg.

The prevalence of hypertrophic pyloric stenosis in our series of 43 patients with Turner's syndrome amounts to 46 per 1,000, which is the same as found by Benson and King.⁴

Turner's Syndrome and Pyloric Stenosis

Author	Number of Patients with Turner's Syndrome	Number of Patients with Pyloric Stenosis	Prevalence
Lindsten ⁷	57	1	18/1,000
Benson and King ⁴	65	3	46/1,000
This study	43	2	46/1,000

According to Benson and King this incidence of 46 per 1,000 is significantly different ($P < 0.01$) from that found in the general population, the incidence for girls being 1 per 1,000, for boys 5 per 1,000. Further evidence is thus added to the hypothesis that the incidence of hypertrophic pyloric stenosis in Turner's syndrome might be higher than in the general population, and might be comparable with the incidence among sibs in cases with familial pyloric stenosis.—I am, etc.,

Medical and Surgical Vagotomy and Intrinsic Factor Secretion

SIR,—In the interesting report by Dr. J. F. Adams and others (19 August, p. 473) on the effect of medical and surgical vagotomy on the gastric secretion of intrinsic factor, these authors cite one of our papers on this subject.¹ We should like to correct a slight misunderstanding concerning the concept "reduction." We expressed the postoperative values in per cent of the preoperative values—that is, the values are reduced to x% not reduced by x%. Thus the intrinsic factor output after operation was reduced to 44%, or reduced by 56%. According to our data the values for volume, acid, and intrinsic factor output,¹ though somewhat higher than the values given by Dr. Adams *et al.*, did not differ significantly from the results recorded by these authors.

It seems then well established that the histamine stimulated intrinsic factor secretion after vagotomy and a drainage procedure is reduced to about half the preoperative values.^{1,2} It is therefore interesting that medical vagotomy does not lead to a significant reduction in intrinsic factor output. This finding is supported by the result of Dotevall *et al.*³ and our own study⁴ on the effect of optimal effective doses of L-hyoscyamine on gastric secretion. In the accompanying Table are shown the mean secretory values in the posthistamine hour for a series of duodenal ulcer patients before and after surgical vagotomy and drainage,¹ and in

	Volume	Acid	Intrinsic Factor
Surgical vagotomy			
Before ..	408	40.4	27.8
After ..	217 (53%)	15.0 (37%)	12.2 (44%)
L-Hyoscyamine treatment			
Before ..	391	43.8	27.2
During ..	284 (73%)	30.8 (70%)	24.3 (89%)

Mean values of volume (ml./hour), acid (mEq/hour), and intrinsic factor (kilo units/hour) in posthistamine hour for male duodenal ulcer patients, before and after surgical vagotomy and drainage, and before and during treatment with optimal effective doses of L-hyoscyamine.

another series of male duodenal ulcer patients before and during anticholinergic treatment.⁴ After surgical vagotomy the output of volume, acid, and intrinsic factor was significantly reduced. During treatment with L-hyoscyamine the values of volume and acid were significantly lower than the pretreatment values, while no significant difference was found for the intrinsic factor secretion.—We are, etc.,

Human Infection with Porcine Ascaris

SIR,—Drs. R. F. Phillipson and J. W. Race (30 September, p. 865) have drawn timely attention to the fact that the pig *Ascaris* can infect man. Some years ago we pointed out¹ that work in this laboratory supported by the Medical Research Council of Ireland suggested that the pig was a source of human ascariasis. Later we concluded² that no biochemical differences could be found between the porcine and human forms of *Ascaris*.

Recently³ we have reviewed the evidence for regarding *A. lumbricoides* and *A. suum* as separate species and shown that there is evidence (for example, Lysek⁴ and Moskalev⁵) that *A. suum* can develop as readily in man as in the pig. Apart from the infection of the gut, porcine *Ascaris* may cause Loeffler's syndrome in man⁶ and sensitivity to the helminth occurs not uncommonly in laboratory workers.⁶—I am, etc.,

Insulintropic Action of Secretin

SIR,—Drs. D. R. Boyns, R. J. Jarrett, and H. Keen in their recent study (10 June, p. 676) were unable to enhance the serum insulin response to an oral or intravenous glucose load in normal subjects by simultaneous duodenal acidification with citric acid. They have therefore suggested that secretin may not play a physiologic role in the regulation of glucose metabolism.

Since the intraluminal duodenal pH of fasting normal subjects may be acid, however, exogenous acidification of the duodenum in these subjects may not stimulate further

secretin release. For this reason we have chosen to study the fasting serum insulin and blood glucose response to duodenal acidification in four subjects unresponsive to maximal histamine stimulation in the presence and absence of an intravenous glucose load.¹ The secretin mechanism in these patients may be presumed intact since (a) they did not have any clinically evident impairment of pancreatic function; and (b) a number of substances other than gastric hydrochloric acid, such as amino-acids and fatty acids, cause the release of secretin.²

Our results support and extend those of Boyns, Jarrett, and Keen.³ Duodenal acidification in all four subjects in the absence of an intravenous glucose load failed to cause a rise in serum insulin or a fall in blood glucose. In three of these subjects duodenal acidification was carried out in the presence of an intravenous glucose load, and in all three there was no rise in serum insulin or consistent enhancement in the rate of glucose disappearance over that observed with the control ingestion of neutralized saline. In addition, the shapes of the individual serum insulin response curves were striking in that while variations existed from patient to patient, in each individual patient the shape was practically identical following either acid or saline. These observations together with those of Boyns, Jarrett, and Keen suggest that the intestinal factor responsible for the more rapid blood clearance of an oral glucose load does not appear to be endogenously released secretin.

In contrast to their findings and those of Dupré, Curtis, and Beck,⁴ however, we were able to demonstrate an increase in fasting serum insulin levels of 54 to 115% with pancreozymin when injected intravenously into two fasting normal subjects. This difference may be explained by the fact that we sampled venous blood within one minute of injection and at closely timed intervals thereafter. Since the peak increase in serum insulin occurred within one minute and subsided within 10 minutes, this transient response may not have been detected by these previous investigators. In view of our preceding findings with endogenously released secretin, however, we feel that this effect of exogenously administered pancreozymin, like that of secretin, is probably of pharmacologic rather than physiologic significance.—We are, etc.,

Oculogyric Crises after Phenothiazines

SIR,—It was interesting to see a report from Drs. E. C. B. Keat and P. J. Toghill (30 September, p. 867) on side-effects from the use of phenothiazine. These bizarre effects were first brought to my attention in 1962¹ and were then described as the

"grimacing syndrome." I reported two further cases,² both occurring in early pregnancy, after the use of prochlorperazine (Stemetil) for vomiting of pregnancy.

A review of the literature was published in January 1962,³ with two further case reports where perphenazine (Fentazin) and trifluoperazine (Stelazine) were the drugs concerned. Bush⁴ reported two cases following Fentazin, one in pregnancy, in 1963. Since then I have seen two further cases, in one of which the resemblance to epilepsy in pregnancy led to initial advice to refrain from holding a driving licence. This advice was reversed when the facts were later reviewed, and the patient remains well five years later. In the second case it was again noticeable that an inability to protrude the tongue when requested was the main diagnostic sign in a middle-aged woman who had had prochlorperazine.

I would join Drs. Keat and Toghill in sounding a note of caution in the use of this useful group of drugs, and this should perhaps apply to their use in pregnancy more than at other times. It should also be added that the recognition of this condition is of the greatest importance, as, if misdiagnosed, it may lead to the patient being labelled as an epileptic or at least submitted to unnecessary diagnostic procedures.—I am, etc.,

Vital Decision

SIR,—The recent correspondence about the resuscitation notice in Neasden Hospital leads one to suppose that not many doctors are aware of the concern of the nursing profession over the whole question of the resuscitation of patients in hospital. Nor do some of our medical colleagues seem to appreciate the extent to which nursing staff are involved in initiating resuscitation in patients suffering from cardiac arrest.

It is the nursing staff who more often than not start to resuscitate the collapsed patient in the "ordinary" wards of a hospital—that is, in other than special areas such as intensive therapy units, recovery units, cardiac-thoracic units, operating-theatres, etc. It is one thing for a citizen to give the "kiss of life" to a dying person in the street—and more and more of the general public are being trained to meet this sort of emergency—but it is quite another thing for an inexperienced junior member of the nursing profession to exercise judgement about which patient (who may already be seriously ill in bed) should be subjected to heroic resuscitation measures. A nurse's instinct is to help to prolong life, but there is understandable reluctance to do so at the expense of more unnecessary suffering on the part of patients and relatives.

The Royal College of Nursing has asked the medical profession to give guidance for each individual patient on the very difficult issue of deciding which patients should be allowed to end their days in dignity and peace because of their medical condition. A survey (see below) which the Hospitals Department of the R.C.N. undertook in July

1966 to find out the extent of the nurse's involvement in initiating resuscitation, and the guidance and instruction given on action to be taken in such circumstances, showed, among other things that in more than half the cases reported in 302 wards in the hospitals where the survey was conducted it was junior student nurses on night duty who initiated the resuscitation.

The results of the survey were published in the *Nursing Times* of 11 November 1966, and were referred to in the *B.M.J.* (*Supplement*, 8 April, p. 15). The fact that other hospitals have similar criteria (though not publicly displayed) to those issued at Neasden seems to have gone unnoticed.—I am, etc.,

CHRISTINE BROWN.

Secretary,
Hospitals Department,
Royal College of Nursing.

London W.1.

SIR,—I hope that the composers of this "soothing syrup" (30 September, p. 814) will not consider the following comments hysterical or ill-informed or be offended by them, as that is not their purpose. A patient who is really dead cannot be revived. If he can be revived he can't be dead, and no one can be certain if he is alive or dead until appropriate measures have been tried and failed. Perhaps this may seem pedantic, but the point I want to make is that *only* the patient has the right to decide for or against attempts at resuscitation and *no one else*.

A doctor's duty in observance of his Hippocratic Oath is to maintain life as long as possible by every means in his power. Furthermore, as euthanasia is still illegal, doctors have no legal right to deprive any patient of appropriate treatment to resuscitate him. We doctors are far from infallible, so every patient, whatever his age or disease (unless he doesn't wish to be resuscitated), should be resuscitated if possible, no matter what his doctor may think about its desirability. No Government or Ministry has the right to saddle doctors or anyone else with this responsibility. To leave the question of life or death to man-made decisions is to open the road to disrespect for the sanctity of life, murder, or even mass murder, as in Hitler's Germany.—I am, etc.,

Gosport, Hants.

G. W. FLEMING.

Paget's Disease in a Family

SIR,—I was very interested to read the paper on Paget's disease by Drs. J. Verrier Jones and Mervyn F. Reed (14 October, p. 90).

I have a patient aged 54 on my list who was one of eleven children. He had five brothers and five sisters. Two of his brothers are now dead; both were incapacitated by Paget's disease.

The remaining brothers are also sufferers from Paget's disease. One of the sisters has the disease to a marked degree. The others appear to be mildly affected. Between them they have seven children, all free from any abnormalities. Also there is no evidence of Paget's disease in parents, grandparent, uncles, aunts, etc.

It appears from the above that only one generation has been affected (all members

having Paget's disease in some form or other).
—I am, etc.,

Sutton-in-Ashfield,
Notts

G. STEIN.

Gritti-Stokes Amputation

SIR,—Mr. Peter Martin and his colleagues' (30 September, p. 837) series of Gritti-Stokes amputations for vascular disease is unrivalled. Their primary healing rate is probably superior to any other reported series of amputations in the elderly atherosclerotic patient.

Knowing of their results, and, like them, disappointed with the through-knee disarticulation in this type of patient, we have tried to combine the benefits of early healing with satisfactory weight-bearing when pylons and permanent prostheses are fitted. To this end it seemed desirable to provide as flat and large a weight-bearing surface as possible, and therefore it was proposed to section the femur just above its condyles (as it is in the true Gritti operation), but to supplement this with a patellar enucleation. Patellar enucleation not only provides better end bearing, but also prevents slipping, avascular necrosis or non-union of the patella, and provides a painfree stump.

We have now carried out this operation on 15 patients, with primary healing in all but two. One patient whose arterial tree was blocked up to the aorta suffered a 1-in. (2.5-cm.) localized loss of his anterior flap. The other, owing to technical faults, suffered a superficial skin loss of his posterior flap.

The patients can often be discharged home, walking on their pylons, three weeks after amputation.—I am, etc.,

St. Bartholomew's Hospital,
London E.C.1. F. E. WEALE.

SIR,—We were delighted to read the recent article by Mr. P. Martin and his colleagues (30 September, p. 837) in which they record their favourable experience with the Gritti-Stokes amputation for the ischaemic limb. There seems to have grown up an unjustifiable prejudice against the Gritti-Stokes amputation, and we have been frankly puzzled by reports^{1,2} condemning the amputation, since to us it seems to possess all the attributes the authors of these reports seek in other amputations. The alternatives they suggest seem far less favourable, and we have concluded that there must be wide differences in the manner of performing a Gritti-Stokes amputation. The paper by Messrs. Martin, Renwick, and Maelor Thomas is timely, since it redresses the balance and focuses attention again upon an excellent form of amputation which has been in danger of being discarded for less satisfactory operations.

Our experience with approximately 100 patients over the last five years accords well with that of Mr. Martin. The operative technique we use is slightly different from that described by him. The first step is to divide all structures behind the lower end of the femur, and this is easily accomplished from either the medial or the lateral aspect. The incision for the anterior flap divides the ligamentum patellae and the quadriceps expansions so that a flap of patella and associated tendon is turned up; the undersurface of the patella is removed with a saw, and the

skill with which this is done is decisive in determining the success of the amputation. Admittedly this requires a knack, but after correct removal of its articular surface the flat face of the patella is very stable upon the cut end of the femur; a few catgut stitches between the ligamentum patellae and the investing fascia of the thigh posteriorly are sufficient to prevent its subsequent displacement. We do not find it necessary to dislocate the knee joint at any stage, since it is removed, together with the leg, when the femur is divided. The quadriceps expansions are sutured to the deep fascia posteriorly and to the various hamstring tendons. With careful haemostasis it is unnecessary to drain, and of course firm bandaging is avoided—only loose dressings are applied.

Perhaps surgeons, uncertain about the best general-purpose amputation for the elderly, will give fresh thought to the Gritti-Stokes amputation.—We are, etc.,

Railroading in Retinal Vessels

SIR,—I was interested in the report of the above condition by Dr. P. J. Tomlin (16 September, p. 722).

The late Dr. Ernest Bulmer, who achieved great distinction in the Birmingham area and also nationally, was house-physician to the then professor of medicine Dr. Lovell Gullund in Edinburgh Royal Infirmary around 1922. It was Bulmer's habit when a death occurred in his ward to rush off immediately with his ophthalmoscope to examine the eyes of the patient. Primarily he did this because of the good view of the retina afforded by the dilated pupils of death. He noted the curious appearances of the retinal vessels, changes which he had never seen in life, and regarded these changes as conclusive signs of death. His discovery of these phenomena were known to his friends and colleagues, and he waxed so enthusiastically about them that, rather irreverently, they were called "Bulmer's breaks."

Whether he ever recorded them in writing I do not know, but as the ordinary signs of death were accepted at that period I am sure no attempt was made to resuscitate anybody who showed these retinal changes. I know that Bulmer, then a young man, regarded them as a confirmatory and most conclusive sign of death.—I am, etc.,

Demonstration Aerosol Inhalers

SIR,—Many patients for whom aerosol inhalers are prescribed do not use them properly, despite the instructions printed on the containers or in the leaflet accompanying it. The only way the doctor can ensure that his patient knows how to use the inhaler effectively is to watch him using it, and if necessary to give him a demonstration. Such a demonstration is likely to be more effective, and to occupy less time, if the doctor can

take an inhalation himself, but most doctors would prefer not to inhale a drug such as isoprenaline.

It would therefore be useful if the manufacturers of pressurized aerosol preparations would provide "demonstration" inhalers, containing only an inert propellant. Doctors and nurses in general practice and in hospital could then use their own personal demonstration inhalers as often as needed for teaching patients how to inhale correctly.—I am, etc.,

Thymic Structure

SIR,—In your leading article "Thymic Function and Disease Processes" (19 August, p. 447) it is stated that the normal thymus contains no lymph follicles with germinal centres.

I would like to refer you to my findings¹ in a survey of 928 necropsy thymus glands. This included a group of 71 apparently healthy subjects killed in accidents in which the incidence of follicular structures with germinal centres was 50% if all age groups are considered, or 70% if only those subjects falling into the 0-39 years' age group are considered. This figure (70%) is identical with that quoted by Castleman² for the incidence of follicular structures in the thymuses of myasthenic patients without thymomas who had a thymectomy. Most such patients fall into the 0-39 years' age group. Although the follicles found in myasthenic patients are usually more numerous than those found in apparently normal subjects, this is not always the case.¹ Some accident victims had follicles just as numerous and as large as have been seen in the most florid myasthenic thymuses.

The overall incidence of follicular structures with germinal centres in 714 hospital deaths was 5%. This increased to 31% if only those patients (58) who died within three days of the onset of their illness were considered.

The implication in your leading article that follicular structures with germinal centres in the human thymus are significant of autoimmune disease is misleading. Thymic follicular structures with germinal centres do occur in a high proportion of healthy human subjects. The incidence decreases with advancing age and with illness.—I am, etc.,

Facial Palsy

SIR,—Therapeutic nihilism can be carried too far. It is well known that Bell's palsy usually recovers spontaneously, and therefore treatment is unnecessary (30 September, p. 815). Nevertheless, in the residual 10% who do not recover there are some who will benefit from decompression of the facial nerve if it is done in time. This small fraction of all cases of Bell's palsy is usually identified

through patients having a complete paralysis, usually of six or more weeks' duration, with normal electrical conductivity of the nerve, and clinical evidence that the lesion is sited in the descending portion of the Fallopian canal. When regular tests show commencement of progressive deterioration of electrical conductivity then decompression of the grossly oedematous nerve is promptly carried out in order to facilitate survival of the remaining nerve fibres with normal electrical conductivity.

The infrequency of this clinical situation makes a random control series impossible, but the repeatedly observed fact by different observers that prompt partial recovery sometimes follows decompression in the situation described above should not be simply dismissed.—I am, etc.,

Hedon, Yorks.

R. G. WILLIAMS.

"Geriatric Emergencies"

SIR,—Dr. D. F. C. Deacon's letter on the subject of emergency admissions for the elderly (7 October, p. 53) raises important issues regarding the function of the acute medical ward in general and particularly in relation to the elderly.

The function of the average acute medical ward is multifarious. Many patients who are admitted, such as those for investigations, or with peptic ulcer, or diabetes for stabilization, fulfil the useful function to the ward of diluting demands on the nursing staff. Nevertheless, as a result of tradition the nurse/patient ratio of such wards is relatively favourable, varying in different hospitals between 2:1 and 1:1. One is a fortunate patient indeed to be admitted to such wards, particularly if one is in the age group mentioned by Dr. Deacon.

On the other hand, the patient admitted into the geriatric assessment unit, however well organized, has to compete for the attention of a nursing staff under continuous demand from other helpless patients. However, it must be pointed out to Dr. Deacon that the modern geriatric assessment unit does not present the picture of the old chronic-sick ward, inasmuch as there are side wards for the dying patient and also provision for the acutely confused patient, either in small psycho-geriatric units attached or in side-rooms. Furthermore, the resources of the fully evolved geriatric unit are geared more adequately to the rehabilitation of the elderly patient both socially and physically. This is particularly true of the hemiplegic, who in the average acute medical ward runs the danger of being relegated to one corner with a label of chronic sick very early in his ward life. Furthermore, the nursing staff of a fully developed geriatric unit, by virtue of specialized training in geriatric nursing, is particularly more attuned to the prevention of the dreadful bedsores than the staff of the average general medical ward.

It is unfortunate, of course, that many geriatric units are relegated to the worst type of accommodation instead of to the best and that an inadequate amount of financial resources from the National Health Service has been devoted to the treatment of this group of the community. It is interesting to note, for example, that the cost to a regional hospital board of an operation on a "blue baby" is about £5,000, although the results are in doubt and even successful results do

not necessarily mean that the baby will grow up into a productive member of society. On the other side of the scale, a member of the community who has been a taxpayer all his life and has never had an illness until he reaches the age of 76 who suddenly develops a stroke or an acute confusional state due to illness runs the risk of being admitted into an inferior type of accommodation where the nurse/patient ratio is grossly inadequate owing to maldistribution of nursing resources. These are the factors which lead to the frustration experienced by Dr. Deacon.

What is urgently needed is a complete re-assessment of work load factors of various departments in the hospital service. These work load factors should be assessed by an industrial team, so that nurse/patient ratios are not determined by indefinables such as pre-existing establishment or status. It is quite obvious that the hospital of the future will have as its centre a main block of beds containing geriatric assessment units and intermediate and long-stay wards for the elderly, and that grouped on its periphery will be small units for other specialties, including day wards for patients who were previously admitted for investigation. In this way nursing staff will be deployed more efficiently, so that the present contradictions so well outlined by Dr. Deacon may in future be avoided.—I am, etc.,

W. FINE.

Liverpool 25.

Lithotomy Position for Forceps

SIR,—I should like to offer support to Dr. A. H. Morley in his indictment of the lithotomy position for forceps delivery (30 September, p. 862). The fact that deaths are still occurring from inhalation of gastric contents shows that the practice still continues.

The hazards often develop unexpectedly. I recall an instance where a patient was sent to the theatre for a forceps delivery, and, as the anaesthetist, I received a message that the operator might proceed to do a caesarean section. One therefore expected the patient to arrive fully prepared for a major operation, and this to include having an empty stomach. She vomited copiously in the early stages of the induction, thus proving the point in the *Confidential Enquiries*: "The only safe assumption in any parturient woman is that the stomach is full." One is tempted to add, "in spite of all assurances to the contrary."

I attribute this patient's fortunate survival to two circumstances. Firstly, a sucker in working order was immediately to hand. Secondly, shortly before I left the hospital common-room for the theatre a fellow-resident with anaesthetic experience told me that when vomiting occurred in an obstetric patient the lithotomy position was "a death trap." This put me on my guard and was a reference to the fact that the lithotomy stirrups, by anchoring the legs, prevent the patient from being turned on her side to prevent inhalation of vomited material.

In such an emergency it is essential that the anaesthetist be given authority to remove the stirrups without question and without delay. Sterility at this point is irrelevant. Indeed, the question should be asked whether in any case of forceps delivery under general anaesthesia stirrups should be allowed to be

used. The legs could be held by two attendants, who could then give valuable assistance under the anaesthetist's instruction should vomiting occur.—I am, etc.,

Huddersfield,
Yorks.

P. DRANSFIELD.

Fallacies in Four Fevers

SIR,—I read with great interest the article by Professor R. S. Illingworth entitled "Fallacies in Four Fevers" (7 October, p. 41). His article does much to banish the old-fashioned concepts of the treatment and management of infectious disease, and confirms the impressions held by many general practitioners in the course of their work. His comments concerning the keeping of children home from school following infectious illness should be given to every general practitioner and local school authorities throughout the country.

Unfortunately in practice it is not always easy to persuade parents and teachers that in fact the child is perfectly able to go to school after a short period of time, as suggested by Professor Illingworth. Only this week I had a child sent home from school nine days after the onset of chicken-pox, despite the fact the child was clinically well and well out of the period of infectivity. This was because the regulations concerning the return to school after infectious disease were last drawn up in 1956 and have never been amended since.

It is to be hoped that this article will abolish once and for all the illogical and absurd treatment and management of these common conditions.—I am, etc.,

Bristol.

JEREMY P. TELLING.

SIR,—Professor R. S. Illingworth's article "Fallacies in Four Fevers" (7 October, p. 41) brought a breath of fresh air to the subject of exclusion from school in the common infectious diseases.

Most local education authorities and their school medical officers follow the advice on periods of exclusion contained in a memorandum issued jointly by the Ministry of Education and the Ministry of Health. The latest edition of this memorandum, that of 1956, suggests the following periods of exclusion:

Measles: 10 days after the appearance of the rash if child appears well.

Rubella: 7 days from the appearance of the rash.

Mumps: 7 days from the subsidence of all swelling.

Chicken-pox: 14 days from the date of appearance of the rash.

While there is room for some divergence of opinion on the question of how many days each disease is communicable, it is clear that these officially recommended periods of exclusion give a wide safety margin, up to seven days in some cases.

So far there have been editions of the memorandum in 1909, 1925, 1927, 1942, and 1956, and each successive edition has reflected changes in medical opinion, and the periods

of exclusion advised have become progressively shorter. Perhaps the time is now ripe for a further revision, to take account of newer knowledge of periods of communicability. Uniformity of practice in excluding children from schools is very desirable, and difficulties arise when doctors follow their own individual fancies in this matter. In a school where the children are patients of different doctors one can imagine the confusion that can occur in a chicken-pox epidemic when Dr. A. excludes children for one week after the appearance of the rash, while Dr. B. keeps them off school until every last scab has fallen off. Teachers and parents who favoured Dr. B's approach would not hesitate to ascribe the natural progress of the disease through the school to Dr. A's "negligence" in letting the children return to school "too soon."

School medical officers being naturally cautious souls, we tend to fall back on the advice given in the Ministry memorandum when consulted about this matter. There is real need for an authoritative up-to-date guideline on periods of exclusion from school.—I am, etc.,

J. M. MORFITT.

Fatal Constipation in the Aged

SIR,—The triad of cardiac failure, constipation, and confusion is well known in geriatric practice; hence rectal examination has come to be regarded as a routine and imperative procedure in the aged. The complications of constipation in the aged are numerous and may sometimes prove fatal. The following report illustrates the point.

Miss A, aged 87, was admitted complaining of constipation and abdominal distension, discomfort, and pain. There was a history of recurrent episodes of these symptoms over two and a half months. In the past she also suffered from coronary thrombosis and had periods of confusion. The present attack of abdominal symptoms was followed by melaena and a clinical picture of colonic obstruction. As she was unfit for surgical intervention, she was treated conservatively. However, three days after admission she died.

Necropsy showed a peritonitis of short duration due to stercoral perforation of a pelvic colon grossly overfilled (1,195 g.) with impacted faecal matter. No new growth was found.—We are, etc.,

Haemoglobin Levels and Dietary Iron

SIR,—The paper by Drs. R. H. Davis, A. Jacobs, and Rosa Rivlin on haemoglobin levels and dietary iron (16 September, p. 711) is most interesting because it provides experimental evidence for some deductions that have so far been rather tenuous.

It is curious that in some recent surveys the amount of anaemia among women is remarkably similar, although the surveys have been conducted in areas which might be

expected to have differing dietary habits and social composition.

Surveys in rural Wensleydale,¹ industrial Birmingham,² and suburban Beckenham³ have nearly all shown a degree of anaemia among women of childbearing age close to 25%, and with the mean haemoglobin levels showing little change since the M.R.C. survey of 1943.⁴ Other surveys give different figures for the incidence of anaemia or mean haemoglobin levels, but without revealing any obvious cause for this in terms of social or geographical factors.⁵⁻⁷

It is known that menstruation plays an important part in this because the incidence of anaemia decreases after the menopause, but dietary anaemia is not uncommon in infancy, adolescence, and in the elderly. Yet the influence of dietary variations is not so far reflected in a detectable form in the haemoglobin surveys mentioned. If the relationship between diet and haemoglobin is as variable as the authors have demonstrated then this absence of correlation is not surprising.

It is, of course, very difficult to obtain an accurate estimate of dietary intake,⁸ those with the poorest intake giving the least reliable results. Moreover, McCance's⁹ tables measure total iron and not absorbed iron. These two may not be equivalent, as has been shown by the radioactive iron studies of Moore.¹⁰

The only survey of haemoglobin levels showing a regional variation is that in the Perinatal Mortality Survey of 1958,¹¹ where haemoglobin levels are lowest in Scotland and the north, and highest in the south-east. The only factor in the Ministry of Agriculture Food Survey of 1961¹² which shows a consistent geographical distribution is that of green vegetables, whose intake is least in Scotland and greatest in the south-east. Whether this is cause and effect is an interesting speculation.—I am, etc.,

Cambridge.

M.A.O. Inhibitor Headache

SIR,—Any patient who is put on to the monoamine oxidase inhibitor drugs should be advised to avoid eating cheese, Marmite, and other substances which combine with the drugs to give a violent and dramatic headache, clinically comparable with a subarachnoid haemorrhage. Cooper *et al.*¹ described the syndrome as a hypertensive crisis. They found that in their series the mean resting level of the blood pressure rose from 125/75 to 180/120 mm. Hg.

I wish to record that in the last two cases seen by me soon after the onset of the

symptoms there was no marked rise in the blood pressure. Mrs. A. B., aged 50, who was on Parstelin (tranlycypromine and trifluoperazine), came home from a meeting and had a large cheese sandwich. Soon afterwards she developed a very severe headache, which she described as if something had struck her on the back of the neck. I was at the bedside within half an hour of the onset of the pain, and I took her blood pressure several times. It varied between 160/90 and 140/80. The latter figure was the norm for this patient. The headache lasted for a week, and kept her in bed most of the time. Her blood pressure after the first day varied from 120/60 to 140/80. This incident took place in 1963, before I realized that cheese was a factor in the problem. Last week I saw a Mrs. C. D., who had been given Parstelin by one of the doctors on our rota. In spite of warnings about cheese, she had had a meal of it, and within half an hour she was laid low with the typical headache, which made her feel sick. I had no prior record of her blood pressure, but when I took it within an hour of the onset of the symptoms it was only 120/80. This is a painful and alarming drug reaction, and in my experience it is not always accompanied by a marked rise in arterial tension.—I am, etc.,

Ibstock,
Leicestershire.

Mercury Perchloride in Surgery

SIR,—The assumption behind the use of mercury perchloride solutions in cancer surgery is that, in addition to a mechanical wash-out action, they have a cancerocidal effect on cells not washed out; or, to use a more modern idiom, that the harmful effects on the cancer cell outweigh the harmful effects on the normal tissues. This half-century-old assumption has not to my knowledge been put to the test. Dr. George E. Moore, whose group at Roswell Park Memorial Institute has intensively investigated the question of local chemotherapy in cancer surgery, informs me that he too does not know of any accurate evaluation of mercury perchloride (personal communication). If such is the case, has not the time come for an accurate evaluation?—I am, etc.,

DAVID PATEY.

Cantharides Intoxication

SIR,—The interesting item in Medical Memoranda (7 October, p. 33) under the heading "Cantharides Intoxication" states that only four cases have been reported in the English medical literature in the past 25 years.

I would mention a short report entitled "Catharidin Poisoning Due to a 'Blister Beetle'" in the *British Medical Journal*, 1960.¹—I am, etc.,

S. G. BROWNE.

Advantages of Health Centres

SIR.—Dr. E. V. Kuenssberg (14 October, p. 108) seems to have read into our letter much that was not there and to have missed the points we intended to make. We were neither criticizing nor underestimating privately financed health centres, merely pointing out the high costs involved, which we felt was an intolerable burden on the young doctor who has recently come into general practice. This was not an armchair criticism, as we have had this information from visitors to the William Budd Health Centre and, in discussions at conferences, from the doctors working in privately owned centres. Certainly there is no possible interpretation in our letter which might infer that we regard private health centre schemes as "hare-brained"; on the contrary we even suggested how these could be run with advantage.

Furthermore, we are well aware of the various conferences on health centres (one of us attended and spoke at the M.P.U. conference earlier this year), but our primary object is to have a conference of health-centre doctors and *not* a conference on health centres.—We are, etc.,

H. I. HOWARD.
E. J. LACE.

Interview Board for North America

SIR.—The Minister of Health is to send out a team whose unenviable task it will be to try to win back a proportion of medical emigrants (30 September, p. 873). Since conditions are so unsatisfactory here it seems probable that some special incentive will have to be offered if this scheme is to meet with any success at all. But if it does meet with a measure of success who will be the most likely to return—the able enthusiast, who has established himself in a new country, or the disappointed emigrant who has found himself no less a misfit in his new surroundings than he did in this country?—I am, etc.,

North Shields,
Northumberland.
DENIS V. CASHMAN.

"Total Family Care" and Fees

SIR.—As one of the "pre-Whittaker" prodigals returned from the more commercial side of the Atlantic, I take some comfort in the vague signs of rescue from one's financial entanglements in the shape of the faltering steps of our ministerial masters into the thorny jungle of "fee for service." At the same time, however, the very tentative nature of these steps does I believe cause some difficulty in the conscientious application of the two opposing principles under which we are expected to operate.

In an attempt to provide what I regard as total family care I am happy to include advice and practical assistance in family planning, a subject which I feel strongly falls squarely within the court of the family doctor, as opposed to the more impersonal health clinic. That I may charge my patients a fee for the initial examination, fitting, and supply of a suitable device or tablet is clearly understood by both doctor and patient. So far so good. I also feel thereafter under a professional obligation to maintain regular checks upon the patient so serviced. But

here the dividing line between my responsibilities under the N.H.S. and those as private medical adviser becomes somewhat less differentiated, and, in common with other objects of an undifferentiated nature, a source of possible future danger. Indeed, to pursue the analogy a step further, in the course of time, and in the light of the very proper encouragement of preventive medicine, this lack of differentiation may deteriorate to frank malignancy. Further I would add that if I am any judge of the expected reaction of patients, at least in my part of the country, I am quite confident that they would be content to pay a moderate fee for this service of aftercare. This willingness to pay for a recognizably useful "check-up" service is a matter which I feel is kept too well concealed in the political undergrowth of the Elephant and Castle.

If I might be allowed to encroach one further inch upon your valuable space, it would therefore be to suggest that we should be allowed to charge any patient over school age, who so requested, a reasonable and agreed fee for one annual "complete physical examination," without fear of contravening our terms and conditions of service. That this fee should be paid by the Ministry as for the other items so covered (though one would hope with less complicated paperwork) is of course a most laudable ambition, which would bring the N.H.S. in line with most if not all the provincial insurance schemes in Canada.—I am, etc.,

Alcester,
Warwicks.

A. F. MADGE.

More Forms

SIR.—It appears that to get a refund of selective employment tax in respect of part-time employees it will now be necessary to make two applications—one to the Ministry of Social Security and one to the executive council.

Bureaucratically this may be excellent, but it makes one wonder whether all the value for direct payments for ancillary staff is not going to be eaten up by the fact that the staff are going to be employed in producing more and more forms for the Ministry and less and less help for the general practitioner.—I am, etc.,

Wolverhampton,
Staffs.

R. S. V. MARSHALL.

Overseas Registration and Seniority

SIR.—I graduated from Punjab University in April 1941, and was registered with the Punjab Medical Council in May 1941. I was eligible for full registration with the General Medical Council, London, from that date, as confirmed by a letter from the G.M.C. dated 9 February 1967.

I have been a principal in the N.H.S. continuously from July 1958. I applied for the first seniority payment and was refused by Birmingham Executive Council on the ruling they received from the Ministry of Health that full registration means registration with the G.M.C. London only. I then applied direct to the Ministry on 9 March 1967 explaining that my registration was equivalent to full registration with the G.M.C. (as confirmed by their recent letter), and that the period should be counted from 15 May 1941. I received a reply in May

1967 telling me that full registration means actual registration by the G.M.C. and that registration with overseas bodies did not count for the purpose of determining eligibility for seniority payment.

While I was awaiting the above reply the Ministry issued a circular, paragraph 2 of which says that registration with the Registration Council of the Republic of Ireland is now recognized for seniority payment.¹ This came into effect from October 1966. While congratulating Irish colleagues on their well-deserved success in obtaining justice, one wonders if it is because the Ministry realizes the absurdity of not recognizing overseas registration, or is it that Eire is still regarded as a British possession?—I am, etc.,

Aston,
Birmingham.

G. MURTAZA.

Points from Letters

Sales Promotion

Dr. H. G. MORRIS-JONES (Dyserth, Flintshire) writes: I was interested to read Dr. J. R. Caldwell's letter on sales promotion (16 September, p. 741). It reminded me of a visit by a young representative some months ago—not knowing that I had retired some seven years ago. In the course of the conversation he said that he knew of two doctors who refused to see travellers, and he wondered how they managed to carry on their work. Such was his opinion of general practitioners. I told him that they probably gave better treatment because they were not bothered with representatives pushing their drugs.

Drinking Doctors

Dr. R. A. DE K. GLOVER (West Horsley, Surrey) writes: Many doctors enjoy, deserve, and feel all the better for a drink or two after a hard day's work. . . . But they have no real idea about how much is required to push their individual blood readings up beyond legal limits. I therefore suggest that they invest in a few breathalysers, and, on a few duty-free evenings, test themselves hourly (for say three or four hours) after one, two, and three drinks of their normal tippie on (a) an empty stomach, and (b) a full one. This would give them some idea of their legal capacity and prevent a great deal of worry or reluctant abstinence.

Melanoma, Halothane, and Liver Necrosis

Mr. M. WHITING (London W.1) writes: The two cases described by Mr. G. S. W. Organe and Dr. G. L. B. Thurston (7 October, p. 49) resemble in some respects those which used to be called "delayed chloroform poisoning" or "post-anaesthetic acidosis."

I had seen two cases of this condition, both in children aged 4 and 7 respectively, who were operated on for acute appendicitis. The anaesthesia was relatively short, 15 minutes for the first, and 30–35 minutes for the second, which had an appendix abscess. Both patients appeared to be doing well the morning after operation, but each later in the day became very restless and vomited frequently. One had a high temperature of 105–106° F. (41° C.), but the other only a moderate temperature of 101° F. (38.5° C.), which became normal next morning. Death took place in each case 36 hours after operation.

Post-mortem examination in the younger patient showed extensive fatty degeneration of the liver; in the older one the liver was yellow and mottled, with fatty degeneration, and the kidneys were pale and enlarged, and microscopically fat was seen in the cells of the convoluted tubules.

These cases differ in some respects from those of Mr. Organe and Dr. Thurston, which were, however, adult patients.

Obituary Notices

F. E. STABLER, V.R.D., M.D., F.R.C.S., F.R.C.O.G.

Mr. F. E. Stabler, senior obstetrician and gynaecologist to the United Newcastle upon Tyne Hospitals, died on 13 October after returning home by car on a stormy night from Southport, where he had been adjudicating in a nurses' contest. He had borne ill-health and pain for many years with remarkable fortitude, and had achieved his avowed object of carrying out his full professional commitments until the day of his retirement on 23 September. He was 65.

Francis Edward Stabler was born on 23 September 1902, and received his medical education at the University of Durham, graduating M.B., B.S. in 1925. He proceeded M.D. in 1928, and was awarded a gold medal; in the following year he took the F.R.C.S. After holding resident appointments in the skin, gynaecological, and general surgery departments at the Royal Victoria Infirmary, Newcastle upon Tyne, he was appointed assistant obstetrician at Princess Mary Maternity Hospital. He later became consultant obstetrician and gynaecologist at the Royal Victoria Infirmary, and consultant at Princess Mary Maternity Hospital. During the second world war he served in the R.N.V.R., and spent a considerable part of his time practising general and traumatic surgery at Chatham, Sherborne, and Trincomalee, attaining the rank of surgeon commander. He was elected Fellow of the Royal College of Obstetricians and Gynaecologists in 1945.

As a member of Council of the Royal College of Obstetricians and Gynaecologists, and as an examiner for the Membership of the College, Stabler concerned himself with the wider field of his subject, while in Newcastle he was an active committee member. He was recently vice-chairman of the House Committee, and chairman of the Medical Staff Committee, of the Princess Mary Maternity Hospital, and of the Medical Staff Committee of the Royal Victoria Infirmary. He was an ex-president of the North of England and Newcastle upon Tyne Obstetrical and Gynaecological Societies, where his lively comments stimulated spirited discussion. In 1957 he was vice-president of the section of obstetrics and gynaecology at the Annual Meeting of the British Medical Association.

Frank Stabler was a very determined man, frank by nature, forthright and outspoken in discussion, and sincere in his opinions. His direct approach and puckish humour made him a popular teacher to students and nurses, in whose education and welfare he always took a keen personal interest. In his professional work he was sound, down to earth, and practical, and reluctant to adopt new techniques until he, personally, was satisfied that they had been proved to be safe and were practicable. However, he strongly supported well-planned research programmes and adequately controlled clinical trials. He was one of the original small team of obstetricians who introduced and operated the Newcastle Emergency Obstetric Service—the "Flying Squad"—in 1935, of which until

recent months he was an active and enthusiastic member.

In private life he had many diverse interests. He loved to visit his cottage in Swaledale, or to fish the waters of the Tyne or Colt Crag reservoir, and he was an enthusiastic wildfowler who, undeterred by adverse weather conditions, would happily spend many cold, wet hours in his punt, stalking duck on the sandy flats between Holy Island and the North Northumberland coast. He was chairman of the Northumberland and Durham Wildfowling Association for some years, and, in addition, with his great interest in bird life and deep concern for nature conservation, he was active in the formation of the Lindisfarne National Nature Reserve, and became committee chairman. In quieter moments of relaxation he became absorbed in the interpretation and working of intricate patterns of tapestry, in which he was very proficient and which gave him great satisfaction.

He will be greatly missed in Newcastle and in many other places where he was a welcome visitor. We extend our deep sympathy to his widow, daughter, and two sons.—W. H.

W. PATRICK, T.D., M.B., CH.B.

F.R.F.P.S.GLASG., F.R.C.S.ED.

F.R.C.S.GLASG.

Mr. W. Patrick, surgeon and director of accident services at Glasgow Royal Infirmary, died suddenly on 14 October as he was playing golf at Turnberry, Ayrshire. He was 66.

William Patrick was born on 5 July 1901, and was educated at the High School and University of Glasgow, graduating M.B., Ch.B. in 1924. After serving early resident appointments at Glasgow Royal Infirmary he joined the staff in 1928. In 1931 he was elected Fellow of the Royal College (then Faculty) of Physicians and Surgeons of Glasgow, and the following year Fellow of the Royal College of Surgeons of Edinburgh. In 1936 he became first assistant to the late Professor J. A. G. Burton, St. Mungo professor of surgery in the University of Glasgow. He served during the second world war in the R.A.M.C. as lieutenant-colonel in charge of a surgical division. He was sent overseas, and was mentioned in dispatches. He was also the holder of the Territorial Decoration. After demobilization he returned to Glasgow Royal Infirmary, and in 1953 he was appointed consultant surgeon. Some years later he became surgeon and director of accident services at the infirmary. In 1962 he was elected Fellow of the Royal College of Surgeons of Glasgow. He retired in 1966.

H. H. P. writes: There will be many sad hearts at the news of the sudden death of Bill Patrick. Patients, colleagues, and a

multitude of friends will mourn the loss of a skilful and decisive surgeon, and a loyal and well-loved companion on every and any occasion. During his school and university days Bill proved himself something of a "natural" at ball games—rugby, cricket, and golf in particular—and indeed at any activity which demanded what is generally called "a good pair of hands." His "Blue" at Glasgow University was gained as opening bat in the cricket eleven, and probably only attention to his medical work, then and thereafter, prevented his achievement of higher honours in this game. It was not surprising therefore that he should follow his father's path, and spend his distinguished medical career as a surgeon. It is, however, of his other qualities that I write here, and of these his modesty takes pride of place. Never from him would one discover the wide spectrum of his medical activity and achievement, or the many facets of his life outside his professional duties. In hospital and out of it Bill Patrick was a perfectionist, demanding always of himself the highest standards in duty and behaviour. Conscientious and considerate for others, he was justifiably intolerant of those who failed to measure up to his standards—for him to undertake a task was to ensure that it was well done.

For many years, and especially since his retirement a year ago, his main recreation was golf, at which he was a stylish and able performer. He founded the active golf club of his infirmary, a conception which has brought relaxation and happiness to many colleagues within and without the hospital. Only his closest friends, of whom there are many, are aware of his pride in the talents of his devoted family. Such friends, and a host of admirers, extend to his wife, son, and two daughters their deepest sympathy in their bereavement.

Major-General F. J. O'MEARA

A.M.S.(RTD.), C.B., M.A., M.D., F.R.C.P.I.

D.T.M.&H.

Major-General F. J. O'Meara died suddenly on 15 October at Ledbury, Herefordshire. He was 67.

Francis Joseph O'Meara was born into a medical family at Skibbereen in the County of Cork on 4 July 1900. He received his medical education at Trinity College, Dublin, and at Sir Patrick Dun's Hospital, where he graduated M.B., B.S., B.A.O. in 1923, and was awarded the Haughton medal and the prize in clinical medicine. He was commissioned into the Royal Army Medical Corps in the same year, and was almost immediately posted to Egypt, where he was to serve for the next six years. During his leave in 1926 he took the M.R.C.P.I., and was elected to the Fellowship in 1928. On his return to England in 1930 he passed the medical specialists' course at the Royal Army Medical College, and obtained the D.T.M.&H. in 1932. From 1935 to 1939 O'Meara

served as medical specialist to Meerut District in India, after which he returned home to join the British Expeditionary Force to France. He was a prisoner of war in German hands from June 1940 to May 1944. Two years after his release he returned to Germany and served as consulting physician to the headquarters at B.A.O.R., where he was very active in touring the hospitals and giving his support to younger medical specialists. From 1950 onwards until his retirement O'Meara was called upon to fill a series of posts in rapid succession: consulting physician to the Far East Land Forces in 1950; officer commanding Queen Alexandra Military Hospital, Millbank, in 1951; deputy director of medical services, British Forces in Korea, in 1952; assistant director of medical services, London district, in 1953; director of medical services, Middle East Land Forces, in 1954; and deputy director of medical services, Western Command, from 1956 to 1959. He was appointed C.B. in 1956, and was honorary physician to the Queen from 1955 to 1959.

O'Meara possessed many fine attributes, both physical and mental, not commonly found in others. Tall, broad-shouldered, dignified, and with a commanding personality he stood out in any company. He had firmly held opinions, which he expressed clearly and forcibly and with no hint of compromise. His somewhat forbidding manner made him a difficult person to know, but once his reserve had been penetrated a warm personality was revealed. The softer side of his nature was readily apparent to young medical officers, who could call on him unreservedly when in need of support. O'Meara was probably at his best and happiest at Millbank Hospital, and many of the patients and staff who knew him in those days will remember him for his wise direction, his firmness, his justice, his staunchness, and for those sudden flashes of humour which were so entirely unexpected.

To his widow and three children, one of whom is a medical officer in the Royal Navy, we extend our sympathy.—R. J. G. M.

I. W. GALLANT, M.D., M.R.C.P., D.C.H.

Dr. I. W. Gallant, a former consulting physician to the Birmingham (Dudley Road) group of hospitals, died suddenly on 27 September. He was 67.

Ian Wolfe Gallant was born on 19 September 1900, and received his medical education at University College Hospital, qualifying with the Conjoint diploma in 1922 and graduating M.B., B.S. in 1925. He held early appointments at the Miller General Hospital and the Evelina Hospital for Children in London and at West Kent General Hospital, Maidstone. In 1927 he took the M.R.C.P. He became assistant medical superintendent at the West Middlesex Hospital, Isleworth, and was clinical assistant at the Hospital for Sick Children, Great Ormond Street, and the Royal Chest Hospital, London. During the second world war he served overseas with the R.A.M.C., and after receiving severe injuries in a road accident in North Africa was invalided out shortly before the war ended. In 1945 he took the D.C.H. and proceeded M.D. in 1949. At the beginning of the National

Health Service he was appointed physician to St. Chad's Hospital and Dudley Road Hospital, Birmingham, where he remained until his retirement at the end of 1965.

L. N. writes: Ian Gallant was basically rather a shy man, shunning the limelight and hiding his true worth. He had had a long schooling in general practice in London before coming into consulting practice after the second world war. Miraculously he survived a serious accident when he was knocked down by an Army lorry, but because of a slight residual disability he was disinclined to the more active pursuits. He was a prodigious reader, and a glance at his bookshelves indicated a catholic taste in literature. But most of all he enjoyed travelling abroad, and during his holidays he could be found somewhere in Europe or further afield. In fact, it was on a trip to Africa immediately after his retirement that he became ill, and he was never really well since that time. The deepest sympathy of his many colleagues will go out to his wife and son.

I. F. ROSE, M.B.E., M.A., B.M., B.CH. F.R.C.S.

Mr. I. F. Rose, deputy surgeon at Manor House Hospital, London, died on 12 October after a long illness. He was 54.

Ian Falconer Rose was born on 3 December 1912, and was educated at Oriel College, Oxford, graduating B.A. in 1935. For his clinical studies he went to St. Bartholomew's Hospital, London, where he graduated B.M., B.Ch. in 1937, and took the Conjoint diploma the same year. After holding early resident posts at St. Bartholomew's Hospital he took the M.A. in 1938. At the outbreak of the second world war he was commissioned in the R.A.M.C. in No. 131 Field Ambulance. Promoted to captain in 1940, he was taken prisoner in Belgium. He spent the next five years caring for British and Allied sick in German prison camps. In 1945 he led 1,200 British prisoners of war from a prison camp in Danzig westward to be liberated by the 7th Armoured Division. On demobilization he spent some months in hospital before returning to surgery. He was appointed M.B.E. for his wartime services.

He held appointments at St. Andrew's and the Metropolitan Hospitals, and became a Fellow of the Royal College of Surgeons in 1947. After an appointment as surgical registrar at Hillingdon Hospital, he became senior registrar at St. Peter's Hospital for Stone, and later at the Royal Marsden Hospital. From 1954 to 1958 he was senior surgical registrar at Chase Farm Hospital, Enfield, before becoming deputy senior surgeon at Manor House Hospital. He filled this post with distinction. He came to Manor House when it was expanding. The hospital acquired some of its consulting staff largely owing to his personal contacts. In particular its urological service was extended by him. The illness of Sir John Nicolson placed an extra burden on him, which he shouldered magnificently. He did two people's work with willingness, humanity, and accuracy. He inspired not only the confidence but the love of his patients and of all who knew

him. In June 1964 he was injured by a car, and soon afterwards he was overtaken by the disease which was to prove fatal. He spent nearly a year in hospital before returning to serve his patients for six months, despite being in constant pain and walking only with the aid of a stick. This was a great blow to one whose abiding passion was walking in the countryside, especially his beloved Cairngorms.

For Ian Rose medicine was a vocation. He devoted his life to his patients, and the Manor House was fortunate in having such a man on its staff. He leaves his wife, who nursed him devotedly, and to whom we offer our sympathy in her grievous loss.—N. S. P.

R. T. PAYNE, M.D., M.S., F.R.C.S.

Mr. R. T. Payne, a well-known consulting surgeon and an authority upon diseases of the salivary glands and on varicose veins, died at his home in London on 20 October, aged 71. He had been ill for many months, but had fought gallantly against increasing pain and disability, and had continued in practice in Harley Street up to the date of his death. The end came suddenly at a time when his health seemed much improved after a short holiday in Somerset.

Reginald Theobald Payne was born on 15 March 1896 at Northampton, where his father had a furniture business. The eldest of four brothers, he had an unusual upbringing, which he described very movingly in his remarkable autobiographical novel *The Watershed*, published in 1961. He was a careful and conscientious surgeon, a man of great sensibility, of considerable artistic talent, and very widely read. His parents had been Unitarians, teetotallers, and vegetarians; and his father was for many years strongly opposed to the tenets of orthodox medicine and surgery, in place of which he favoured a highly personal form of hydrotherapy. Reginald thus came into headlong conflict with his father's ideas at the time when, after grim and illuminating experiences during the first world war, he decided to take up medicine. It is a tribute to the characters of both men that they remained on good terms. Payne qualified with the Conjoint diploma at St. Bartholomew's Hospital in 1923, and was successively house-surgeon and chief assistant to a surgical unit there. He also held appointments as clinical assistant at St. Peter's Hospital, and registrar at the Royal National Orthopaedic Hospital. He was elected Fellow of the Royal College of Surgeons of England in 1925, and graduated M.B., B.S. in 1927. In 1932 he took the M.S., and proceeded M.D. two years later. He was Hunterian Professor of the Royal College of Surgeons of England in 1929 and 1932, and again in 1936 and 1938, and was Erasmus Wilson lecturer in 1931.

Payne was a great individualist and did not work easily—outside the operating-theatre—as a member of a team, but his patients and friends will always remember him for his kindness and humanity, and for his richly stored mind, which made him a delightful companion.

He was married and had two sons, the elder of whom is a pathologist at Glasgow, and the younger a clergyman.—F. H. K. G.

A. S. JARRETT, M.Sc., M.D.

Dr. A. S. Jarrett, who became director of the Royal Naval Physiological Laboratories at Alverstoke nine days before his death, died in London on 10 October. He was 35.

Antony Smith Jarrett was born on 10 May 1932, and received his education at University College, London, graduating B.Sc. in physiology in 1953 and M.B., B.S. in 1957. After an appointment as assistant lecturer in physiology at University College in 1960 he became a surgeon lieutenant-commander in the Royal Navy. From 1962 to 1965 he held an appointment at the R.A.F. Institute of Aviation Medicine at Farnborough. His work there led to an appointment in the Royal Navy as specialist in physiology. He proceeded M.D. in 1965 and took up an appointment as medical director of Syntex Pharmaceuticals, which involved him in a good deal of travel to various parts of the world. In October 1967 he was appointed director of the Royal Naval Physiological Laboratories at Alverstoke.

He leaves a widow and two sons.

D.M.D. writes: Tony Jarrett's interest in the problems of escape from submerged aircraft and of respiration on immersion began in 1962, when he took part in experiments that measured the rate at which modern aircraft sink under water. The following year, in association with Dr. "Cam" Wright, he carried out important work estimating the physiological tolerance to underwater ejection. This was succeeded by "live" trial ejections from Buccaneer and Vixen aircraft. The remainder of his time at the R.A.F. Institute of Aviation Medicine was spent studying the effects upon respiration of partial and deep submersion. This work was published as his M.D. thesis, "Breathing at Increased Ambient Pressures." He was regarded as one of the most talented and colourful scientists to pass through the institute, and will be greatly missed.

D.M.M. writes: It is particularly sad that this most likable young doctor should have died when he had just achieved his long-standing ambition of becoming director of the Royal Naval Physiological Laboratories. His growing authority on medical matters, brilliantly demonstrated at the symposium on breast cancer which he organized for 150 consultants in Caius College, Cambridge, in September of this year, would have ensured the Navy of international leadership in physiology problems for many years to come.

**K. S. MAURICE-SMITH, M.R.C.S.
L.R.C.P.**

Dr. K. S. Maurice-Smith, a well-known general practitioner in East Anglia, died peacefully on 15 October, at the age of 66 years.

Kenneth Samuel Maurice-Smith was born on 28 November 1900. He studied medicine at St. Bartholomew's Hospital, London, qualifying with the Conjoint diploma in 1924. He was appointed resident medical officer at Gravesend and North Kent Hospital, and later became a surgeon to the Blue Funnel Line. In 1928 he entered general practice and settled in Ely. For some 30 years he was medical officer of health for the Ely

urban and rural districts, and held additional appointments as Treasury medical officer to the Tower Hospital, Ely, and honorary medical officer of the Ely Palace Convalescent Hospital. He took a great interest in the St. John Ambulance Association and Brigade. During the second world war this involved intensive lecturing and travelling at a time of increased practice commitments. He became County Commissioner of the Brigade in Cambridgeshire. In 1951 he was made a Knight of the Order of St. John.

Until a year ago he was a member of the General Medical Services Committee and chairman of the Infectious Diseases Subcommittee. For the past 25 years he was the elected representative at the Annual Conference of Local Medical Committees. He was chairman of the Cambridge and Isle of Ely Local Medical Committee, vice-chairman of the Cambridge and Isle of Ely Executive Council, and a member of many other committees. An active member of the British Medical Association, he was chairman of the Isle of Ely Division in 1938-9, 1951-2, and again in 1960-61 and 1962-3, and was president of the Cambridge and Huntingdon Branch in 1957-8, and had for many years served as a representative at the B.M.A. Annual Meeting.

His interests included hockey, climbing, rally-driving, and photography. He was commodore of the Ely Sailing Club, and a past-president of the amateur dramatic society. He had a great interest in boxing, and was president of the boxing club. Of special concern to him was the provision of guide dogs for the blind. He was held in high regard not only by his colleagues in the profession but by all sections of the community as well. His great interest was the British Medical Association, and he was always conversant with the many and varied issues of the day. He was very concerned that all doctors should understand these issues before making a decision. Those who sought his help were always sure of friendly advice. He will be remembered for the vast amount of work he put in on behalf of his colleagues. Our sympathy goes out to his widow and to his son, who was in practice with him at Ely.—G.L.K.

**E. A. ANDRADE, M.B., B.S.
D.OBST.R.C.O.G.**

Dr. E. A. Andrade, a general practitioner in Hereford, died after a motor accident on 10 October. He was 45.

Edward Anthony Andrade, son of Professor E. N. da C. Andrade, F.R.S., was born in London on 14 May 1922, and was educated at St. Paul's School. He received his medical education at University College Hospital, where he was awarded the McGrath scholarship in obstetrics, and graduated M.B., B.S. in 1944. After an obstetric house-surgeon's post at his teaching hospital he served for two years as surgeon lieutenant in the R.N.V.R. During the next four years he held several resident appointments, and took the D.Obst.R.C.O.G. before going into general practice in St. Martin's, Guernsey. In 1960 he moved to Hereford, and went into partnership with Dr. Cyril Francis. He also held the appointment of clinical assistant at St. Mary's Hospital, Burghill, Hereford.

A member of the British Medical Association, he was chairman of the Guernsey and Alderney Division in 1958-9, and secretary of the Division in 1959-60.

B.E.M. writes: Tony Andrade was outstanding both as a doctor and for the wide range of his pursuits. To his fluent French and Spanish were added a useful knowledge of Greek and a recent "O" level pass in Russian. He was widely travelled. His special interests were art, music, and photography. It is as a family doctor that he will best be remembered. His patience and sympathy were inexhaustible, and he was particularly successful with patients whose social and psychiatric problems seemed to others to be insoluble. Somehow he always found time to attend postgraduate courses and meetings, and his standards in obstetrics and medicine were exceptionally high. He was a man of great charm and modesty whom all his patients will mourn as a friend.

Our sympathy goes out to his widow and family.

C.F. writes: Dr. Andrade came to me in April 1960 as an assistant, and within three months he became a partner, which position he held until his untimely death. He proved himself to be a very quiet, deep-thinking, and conscientious worker, with a great interest in all he undertook. By his calm manner, perseverance, and thorough work he soon gained the confidence of the patients. Apart from his profession he took a great interest in languages, speaking French and Spanish fluently; more recently he undertook a course in Russian, which enabled him to spend his recent holiday in Russia. He had resumed work only the week before his tragic death.

He will be missed by many, and the sympathy of his patients and of his friends will go out to his wife and stepdaughter.

**G. J. MURRAY, M.D., M.R.C.P.
D.T.M.&H.**

J.B.R. writes: When Gerry Murray (obituary, 9 September, p. 686) came to Hexham in 1950 he set to work to build up an efficient medical department from its very early beginnings, and within a few years had succeeded fully in that aim. For a number of years he bore a responsibility which weighed heavily on him at times as the sole consulting physician to the Hexham group of hospitals. I was closely associated with him from his early days in Hexham, at first as medical registrar, and valued deeply the friendship which grew up between us through the years. He was always keenly interested in the welfare of the medical and nursing staffs of his department, and never hesitated to support them when the need arose. He was a good clinician with a great understanding of patients as people, and many of his former patients expressed their deep concern during his long final illness. In difficult cases his common-sense approach usually led him to a correct diagnosis through a careful examination, when others might have been misled through the results of equivocal or conflicting investigations. Despite the illnesses of his later years his sense of humour never left him and enlivened many a ward round. Those of us who knew him well will not easily forget him.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 7 October (No. 40) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Eire in Second Quarter

The birth rate in Eire during the second quarter of 1967 was 23.1 per 1,000 population, and was 0.2 above the rate for the second quarter of the previous year. The infant mortality rate was 25 per 1,000 registered births, the same as in the previous June quarter. The neonatal mortality rate was 17, which was 1 above the rate for the preceding June quarter. The death rate, at 10.9 per 1,000 population, was 1.8 below the rate for the second quarter of 1966.

Sixty-three deaths were attributed to respiratory tuberculosis and eight to other forms of tuberculosis. These deaths were 13 fewer and 1 more, respectively, than in the pre-

ceding June quarter. Deaths from infectious diseases included 42 from gastroenteritis under 2 years, 32 from influenza, 4 from measles, and 2 from whooping-cough. Of the 1,279 deaths attributed to malignant neoplasms 527 were due to growths of the digestive system and 208 to growths of the respiratory system.

Accidents at Work

In 1966 in Great Britain 18,533 accidents were reported under the Offices, Shops, and Railway Premises Act, 1963. Of these accidents 29 were fatal. The total number

of accidents was 7.7% higher than in 1965, but the fatal accidents were fewer than the 34 in 1965, and the proportion they comprised of total accidents also fell from 0.19% in 1965 to 0.15% in 1966. The increase in total number of accidents is thought to arise from a greater awareness of the need to notify them. Of all classes of premises inspected under the Act railway premises were found to be the least satisfactory.

In the enforcement of the Act the authorities relied generally on advice and guidance, but during 1966 there were 147 prosecutions involving 300 charges, of which 276 ended in conviction.—*Report by the Minister of Labour for the year ended 31 December 1966, 1967, H.M.S.O.*

MEDICO-LEGAL**Cautionary Tales**

[FROM OUR LEGAL CORRESPONDENT]

It is a little depressing to be reminded by the annual reports of the Medical Protection Society and the Medical Defence Union that the complaints of retained swabs or instruments, and of operations on the wrong side or wrong part of the body, still form a substantial part of the defence societies' work. Mishaps arising from the misuse of intravenous plastic catheters also continue to be reported, though there can be little doubt that the warnings given of the precautions required are having some effect.

Inadequate Premises

A bad system or inadequate premises may be as important a contribution to a mishap as momentary aberration of a practitioner. When a man attended an outpatients department with an indecipherable general practitioner's letter, he was noted in that department as having a left inguinal hernia. On admission, the accuracy of that entry was not properly checked and not altered, and the operation was made on the left side instead of on the right as in fact required.

In another case the personal error of the surgeon (following careful preoperative discussion) was corrected by the anaesthetist but not before a right loin incision had been made when exploration of the left kidney was intended. In another hospital the absence of a proper recovery ward contributed to the death of a patient recovering from a ureterolithotomy. Representations had been made to the hospital authority before this fatality, and following it a recovery ward was provided. But when the dangers involved in carrying women in labour (often anaesthetized) down two flights of narrow stone stairs from the labour ward to the operating-theatre were pointed out to another hospital authority action was delayed pending alterations in two years' time, on the ground that no untoward incident had as yet occurred. Whatever the prospects of resultant activity hospital practitioners would be well advised to make representations

regarding inadequacies of system or premises.

The Medical Protection Society expresses grave concern at doctors' failure to read radiologists' reports, either deliberately or because "sometimes the hospital system almost seems to be designed to prevent a radiologist's report from being seen." For example, a doctor discharged a patient from a casualty department after failing to detect any bone injury on the wet film provided after an x-ray taken because of a history of falling through a skylight. A radiologist's report delivered the following day drew attention to a fracture of the medial malleolus, but in the absence of any system of bringing the report to the attention of a clinician the report was filed away. Four doctors saw the patient in the ensuing month without being aware of the radiologist's report of the fracture.

Accidental Infection

Accidental infection may occur in various ways. One patient contracted a blistered hand and cellulitis of the forearm from vaccinia infection incurred during pinprick testing on the hand (with a needle taken from a box on the practitioner's desk). Another patient, a long-haired young woman, contracted a tetanus infection from a hairpin which had found its way under a full body plaster applied to correct a severe idiopathic scoliosis of the lower thoracic spine. The infection nearly killed her and required premature removal of the plaster rendering that treatment useless. Before further treatment in another hospital, the surgeon insisted that the patient's hair must first be cut short, and the need for the hairpins removed.

Drug addiction will no doubt cause increasing trouble in future years. A much publicized case in which a legally aided patient who sued his doctor after becoming addicted to the Omnopon prescribed for him has been settled. The publicity given to this case may well encourage others of a similar nature. Balancing the risk of addiction

against the benefits to be gained from a drug will often call for difficult decisions, which will not be held negligent merely because with hindsight they may appear mistaken.

But simple human carelessness continues as a major cause of injuries to patients. For example, the Medical Protection Society points out that every year a number of claims are made arising from the use of trichloroacetic acid, "and perhaps no other topical application is responsible for such extensive demands on the Society's finances, as such claims are usually indefensible."

Third Party Insurance

Insurance with a medical defence society remains a best buy for doctors. But it is not enough. In addition third party insurance of surgery and consulting-room premises is desirable in case of accidents to patients. And personal accident and sickness insurance should be considered to guard against loss arising out of an accident suffered by the doctor, for example when driving his car, or when being driven in one of the fashionable "flying squads."

The Medical Defence Union's report refers to "a barrister" who is alleged to have consulted a Fellow of the Royal College of Physicians and then declined to pay his fees, relying on the College's by-law which prevents Fellows from suing for their fees. This paragraph caused considerable dismay among members of the Bar, and the Bar Council asked the Medical Defence Union for the name of the barrister. Although it is said that the physician had employed debt collectors to try to recover the debt, he is apparently unwilling to disclose the name of the barrister concerned to the Bar Council and no complaint has been made to the Bar Council. In a letter to *The Times*, the Chairman of the Bar Council has said that he could not believe that the barrister concerned was a practising member of the Bar. At a time when relations between the professions are improving, it is a pity that such allegations should be made in general terms without particulars. If a complaint were laid before the Bar Council (or any other professional body, one would think) disciplinary steps would certainly follow.

PARLIAMENT

Key Amendments Reversed in Abortion Bill

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The passing of the Abortion Bill was assured after yet another long debate in the House of Lords on 23 October. On both the contentious issues which had resulted from amendments made by the House of Lords last July—the condition that one of the doctors whose opinions were to authorize the termination of a pregnancy should be a Health Service consultant, and the vote to remove the risk of injury to existing children of the pregnant woman—the Lords surprisingly reversed their previous decisions, and so removed the possibility of conflict with the majority in the House of Commons that had passed the Bill.

One final alteration, in the form of a manuscript amendment by VISCOUNT DILHORNE, was left for the Commons to decide. This would permit a third medical man, after the other two had given their opinion, to perform the operation. While LORD KENNET saw a difficulty here, that the doctor who actually did the operation could not be prosecuted, LORD SILKIN was disposed to accept it, at least to give the Commons an opportunity to consider it, but he did not want it to become a constitutional issue if the Commons did not agree.

The amendment was agreed to, and so the Bill reached the end of its course through the Lords and appeared safely set on the way to the Statute Book.

Restriction on Practices

LADY STOCKS (Lab.) moved the amendment to Clause 1 to delete the requirement that one of the two doctors giving an opinion in favour of termination on the stated grounds must be a Health Service consultant or a doctor approved by the Minister of Health.

Her reasons were that consultants were few and far between, and it might be difficult for a woman in a rural area to find such a consultant. She added there would be a tendency to push distressed women into the hands of the back-street abortionist.

The clause would also have an effect on private practice. It was not the business of the Bill to restrict the area of private practice, but the clause if passed unamended would have that effect.

If the clause was unamended, she feared it would wreck the Bill. It would not be accepted in the Commons. Those who were anxious to rationalize and legalize the present position would have to start all over again with a new Bill in both Houses.

VISCOUNT DILHORNE said the House had already debated this question and expressed its opinion in no uncertain words. The words which it was now proposed to delete from the Bill had been put into it by a vote of 167 to 116.

There was far less risk of collusion and of the Harley Street racket developing throughout the country if there was the requirement that one of the two opinions must be that of a consultant employed in the Health Service.

It was better to keep this provision in the Bill than leave it wide open for newly called doctors to engage in a racket.

LORD BROCK said there were nearly 9,000 consultants in the National Health Service; nearly 6,000 of them were part-time. There was therefore no restriction on choice. The amendment would ensure a higher standard of advice and treatment to the pregnant woman.

VISCOUNT WAVERLEY said the amendment would not only check collusion between two doctors in practice together but would ensure expertise in the treatment of the pregnant woman.

LORD SOPER (Lab.) said that he was not concerned with promiscuous girls of 15 or 16 or frivolous married women who were pregnant by a man other than their husbands, but with the other 80% of abortion cases involving women for whom another pregnancy was an intolerable prospect.

He had great difficulty in reconciling what had been said about the number of consultants available and figures which had been published, and which indicated there were 740 consultants available unevenly distributed throughout the country.

If the provision were allowed to remain in the Bill there would be delay, and delay in the early stages of pregnancy was a devastating experience for a woman, especially one faced with the intolerable prospect of another child. It was in order to reduce suffering that he thought the amendment should be accepted.

The ARCHBISHOP OF CANTERBURY said that when he supported the insertion of the words Lady Stocks proposed to delete he did so for two reasons: to help prevent a racket by some doctors, and to ensure the highest standard in connexion with abortions. These reasons still seemed to stand.

Not for the first time, but more forcibly, it was suggested that consultants were so scarce or so inaccessible that women would resort to back-street abortions. But were consultants inaccessible?

Was it beyond the power of the Ministry of Health to see that if the Bill were passed in its present form the necessary provisions were made? Was it not the duty of the Government to see that what the Bill asked for was provided? Was it possible to have a social reform of the kind envisaged without a commensurate action on the part of the Government to see that it worked?

Collusion Discounted

LORD SILKIN (Lab.) said that at present it was possible for an abortion to take place quite lawfully with only one doctor. This Bill provided for two doctors as a safeguard. Most people felt there should be a second opinion. The issue was what the nature of the second opinion should be.

Much had been made of the danger of collusion, but what was meant by that? Was it that two partners in practice would start

a racket of freely giving authority for abortions? But a panel patient could not be charged, and it would be quite unlawful to ask for a fee for performing an abortion. The paying patient was not the problem—she would be able to find her way to Harley Street. Surely if doctors could not charge a fee there was no incentive for collusion.

He asked the House to reconsider its vote on the last occasion and to vote for the amendment.

LORD KENNET, Parliamentary Secretary, Ministry of Housing and Local Government, said that last year there were 521 obstetric and gynaecology consultants in England and Wales. He could not say that no bottleneck would be introduced by the enforced employment of these consultants.

In the gynaecological departments of N.H.S. hospitals the average delay in getting an operation in non-emergency cases was about six weeks at the moment. No Minister of Health had ever arrogated to himself the right to say that one class of doctor should carry out a surgical operation and another should not. The present Minister was unwilling to be the first to arrogate that right to himself. On the question of collusion and rackets, he said that one could not be certain that a consultancy indicated a superior degree of morality and social conscience.

Although this was very much a question for the House, in the Government's view the amendment was quite acceptable.

LORD SEGAL (Lab.) said there was no use in obtaining a second opinion if it was to be given by a doctor with the same qualifications as the first doctor, and who would merely rubber stamp what had already been said.

There was a list of general practitioners skilled in midwifery. It was a list approved by the medical bodies. Those on it had certain qualifications in midwifery. There was therefore no need for the Minister to draw up such a list.

The amendment was carried by 113 votes to 79—majority 34.

Effect on Existing Children

LORD SILKIN moved an amendment to restore to the Bill the words "or any existing children of her family," thus permitting an abortion if there was a risk of injury to any existing children from the birth of another child.

He said the amendment dealt with what had become known as the social clause, a term which was quite wrong. It was a provision that in considering the circumstances of the pregnant woman the doctor had to take account of her total environment or of the circumstances of the existing children.

There were cases, few in number, where the injury to the existing children would be severe and ought to be taken into account by the doctors who were going to decide whether an abortion should take place.

LADY SUMMERSKILL (Lab.) said they were concerned with the masses of people who lived in the industrial areas of the towns: the slums, where adolescents slept in the same

room and where families were kept awake at night by a crying child.

We plead, she said, for those families where the family is already so big that the wife is harassed and where the husband is so bad-tempered that he stays out at night in the public-house, arrives home drunk, has sexual intercourse, and produces another child.

LORD STONHAM, Minister of State, Home Office, said he could think of many cases where another pregnancy could affect the health of existing children. There were cases where the social circumstances of the family might be worsened by an addition to the family. There could be cases in which the doctor's knowledge of the family circumstances enabled him to form an opinion.

The ARCHBISHOP OF CANTERBURY said he was always ready to change his mind in the light of new evidence or facts. In the earlier debate that evening he had asked for information about matters that were obscure, and the information forthcoming sufficed to tilt the balance of argument in his mind.

On this amendment he was ready to hear anything to cause him to change his mind, but he had heard nothing to lead him to think it was right that the House should reverse the decision made a few months ago.

THE MARQUESS OF SALISBURY (Con.) said that Lord Silkin and his friends in all sincerity asked the House to take a far-reaching step. It was a very dangerous one.

It was one thing to say that an abortion was justified because the birth of a child

would involve risk to the health of the mother. That was a question of medical opinion. The decision to allow an abortion on further social grounds was a very different thing. Who was qualified to judge what would endanger the health of one or more of the existing children?

If there was a referendum, and he sometimes thought there was a case for a referendum on such issues as this, he believed it would be decisively defeated.

Decision Should be Free

LORD CARRINGTON (Con.) said he hoped members would not be influenced in the way they voted because of the fear of a constitutional crisis. He did not think it should, or could, arise on this Bill.

If ever there was a Bill on which peers should vote according to their consciences this was it. There should be no threats, he said, by the newspapers, the Government, or anybody else, which should deter them from doing what was right.

LORD STONHAM repeated that the Government were neutral. The people were not concerned about the constitutional issue. They and most members of the House wanted their discussions to result in a viable Bill.

The amendment was carried by 86 votes to 69—majority 17.

The Bill was agreed to on third reading, and was finally passed without a division.

Ban on Cigarette Coupons

The MINISTER OF HEALTH told the Commons on 23 October of his decision to ban cigarette coupon and other promotional schemes, and to limit expenditure on advertising cigarettes.

Last month, he said, in answer to a question by Dr. JOHN DUNWOODY (Falmouth and Cambourne, Lab.), the manufacturers had told him of their failure to reach a voluntary agreement. Two of the firms would agree to the ending of coupon schemes and to the limitation of mass media advertising expenditure on a basis agreed between them. The third firm would not agree to the ending of coupon schemes, though they would have been prepared to control their development and to limit advertising.

After more than a year of negotiations, he continued, it was now clear that no further progress was possible by voluntary agreement. Cigarette-smoking was a serious danger to health and a major cause of preventable deaths. In view of this the Government had decided to introduce legislation in due course to take powers to ban coupon gift schemes in relation to cigarettes, to control or ban other promotional schemes, to forbid or limit certain forms of cigarette advertising, and to limit expenditure on advertising of cigarettes.

Mr. B. WHITAKER (Hampstead, Lab.) asked him whether he would now take steps to compel all cigarette manufacturers to print on their packaging and advertising a warning of the danger to health. Mr. ROBINSON: Not at present.

MEDICAL NEWS

Professor in Experimental Pathology

The title of professor in experimental pathology has been conferred on Dr. LYNNE REID by the University of London in respect of her work at the Institute of Diseases of the Chest, Brompton Hospital, London.

Dr. Lynne Reid graduated in 1946 at the University of Melbourne. After various clinical appointments she became a member of the Royal Australian College of Physicians, and was appointed a research fellow of the National Health and Medical Research

Council of Australia in 1949. In 1951 she joined the Brompton Hospital as a research assistant, and became a member of the Royal College of Physicians in 1952. In 1955 she joined the Institute of Diseases of the Chest when she started the research department of morbid anatomy and experimental pathology, becoming full-time senior lecturer and reader. In 1964 she was elected a fellow of the Royal Australian College of Physicians. She is honorary consultant to the Brompton Hospital, a foundation member and fellow of the College of Pathologists,

and a member of the Medical Advisory Committee to the Cystic Fibrosis Foundation. The work of her department has been particularly concerned with the morbid anatomy of chronic bronchitis, cor pulmonale, and emphysema.

Royal College of Obstetricians and Gynaecologists

The President of the Royal College of Obstetricians and Gynaecologists, Sir JOHN PEEL, presided over a large company at the annual dinner of the college on 18 October, held for the first time in the college's own premises. Sir JOHN WOLFENDEN, Chairman of the University Grants Committee, proposed the toast of the college. The PRESIDENT replied. The toast of the guests, proposed by Mr. ANTHONY ALMENT, was responded to by Mr. GILBERT EDGAR.

Joint Consultants Committee

Sir JOHN RICHARDSON was elected chairman and Mr. WALPOLE LEWIN was elected vice-chairman of the Joint Consultants Committee at the Royal College of Physicians and Surgeons of Glasgow on 24 October. Warm tributes were paid to Sir THOMAS HOLMES SELLORS, who had been chairman for nine years.

General Practice Teaching Unit

The Nuffield Foundation has given the sum of £33,000 to Guy's Hospital Medical School to establish a general practice teaching unit based on Thamesmead. This sum is additional to the £35,000 given by the

Foundation in 1964 to establish the general practice research unit at Guy's to develop the Thamesmead health services project. Dr. ROBERT SMITH, until recently seconded from the Wellcome Foundation to head the Guy's G.P. Research Unit, has been appointed director of the general practice teaching unit, attached to the department of medicine.

Postgraduate Medicine, 1967

A series of six weekly programmes for doctors has been produced jointly by Scottish Television and Tyne Tees Television in association with the Glasgow Postgraduate Medical Board and the Organization for Postgraduate Medical Education, Newcastle upon Tyne. The first title, with time of transmission, is announced under "Coming Events" (p. 247), and the announcements will be continued each week.

Postgraduate Medical Education

For the next year the offices of the Central Committee on Postgraduate Medical Education (Great Britain) will be at the Royal College of Physicians, St. Andrew's Place, London N.W.1.

Research into Mental Retardation

An institute to co-ordinate and promote research into mental retardation has been established under the sponsorship of the National Society for Mentally Handicapped Children. It will provide an information service, and plans to organize conferences, symposia, and study groups. A scientific

library, initially for reference, is being built up. The chairman of the institute is LORD FRANCIS-WILLIAMS and the vice-chairman Dr. DAVID MORRIS. Its address is 5 Bulstrode Street, London W.1.

Club for Doctors and Engineers

Doctors and engineers in the Manchester area have formed a medical-engineering club to encourage the use of engineering techniques in medicine. Some 50 members of the staffs of Manchester University and Salford University as well as consultant surgeons are said to have applied for membership. Professor J. H. KELLGREN, professor of rheumatology at Manchester University, is president of the club. The secretary is Dr. JAN SKORECKI, senior lecturer in mechanical engineering at the University of Manchester Institute of Science and Technology.

Dr. Raymond Hoffenberg

A deputation from Cape Town University was received by the Minister of Justice, Mr. PETRUS PELSER, on 19 October and discussed the case of Dr. RAYMOND HOFFENBERG, senior lecturer in the department of medicine, who has been served with a banning order (see *B.M.J.*, 26 August, p. 512). It consisted of Dr. J. P. DUMINY, principal of Cape Town University, Mr. HARRY OPPENHEIMER, the Chancellor, Mr. CLIVE CORDER, chairman of the university council, and Professor JOHN F. BROCK, head of the department of medicine.

Overseas Students in Universities

Clinical medicine ranked highest as a field of study among overseas students enrolled at British universities 1966-7, according to a report by the Association of Commonwealth Universities. The figures were undergraduate (504) and postgraduate (790). Altogether there were 17,659 full-time overseas students in universities at the beginning of the academic year. More than half (9,584) were Commonwealth students. The countries from which the largest numbers of students came were U.S.A. (1,991), India (1,711), Pakistan (952), and Nigeria (904). Copies of the report can be obtained from the association's office at 36 Gordon Square, London W.C.1.

Nobel Prizewinners

A Swede, Professor RAGNAR GRANIT, and two Americans, Professor HALDAN KEFFER HARTLINE and Professor GEORGE WALD, share this year's Nobel Prize for medicine. Their work is referred to on page 185.

Artificial Kidney

With the support of the National Research Development Corporation a research group at Leeds University, under the direction of Professor G. G. HASELDEN, is attempting to produce a disposable plastic kidney. Professor Haselden describes the project as follows:

The short-term aim is to produce a low-cost sterilized dialyser which may be disposed of after use, thus reducing infection hazards and labour requirements in hospital units. In terms of function it is hoped that the new unit will perform in a way similar to that of the Kiil dialyser, while offering the advantages of disposability at present restricted to the several designs based on the twin coil kidney. The unit has been designed with the prime objective of forming a cheaper, more convenient, and safer substitute for the Kiil, without any loss in dialyser performance. It will be quite compatible with existing monitor units.

The long-term aim is to produce a self-contained dialyser which does not depend on an external source of dialyser fluid. The present dispensers of dialysis fluid and associated monitoring devices represent the major capital cost of the entire artificial kidney machine and inevitably present servicing problems which use scarce labour. The self-contained dialyser will use a small volume of fluid contacting a bed of adsorbent and ion exchange resin. Work at present is concerned with the evaluation of suitable adsorbent materials.

Occupational Medicine

An exhibition of various aspects of occupational medicine is being held in the Claire Wand Gallery, B.M.A. House. Organizations represented include the M.R.C. Pneumoconiosis Research Unit, Group Industrial Health Services, London Transport Medical Service, Steel, Peck and Tozer (medical department), and the Scottish Occupational Health Laboratory Service Ltd. The exhibition will be open to members during library hours until 10 November.

M.R.C. Fellowships and Training Awards

For the academic year 1967-8 the Medical Research Council has awarded 23 junior research fellowships and 466 training awards. The fellowships are intended for medical and dental graduates with some research experience or for science graduates holding a postgraduate degree. Scholarships for training in research methods and awards for further education in the medical sciences enable young graduates with medical, dental, or science degrees to continue training beyond a first degree. The training awards also include awards for intercalated courses. These are intended for medical and dental students who have completed the second M.B. and B.D.S. examinations and who wish to undertake a course in a biological science before proceeding to their clinical studies.

Coming Events

British Medical Association.—"The Effectiveness of Television in Medical Education," lecture by Professor I. R. MERRILL, of the University of California, 16 November, 5 p.m., B.M.A. House, London W.C.1.

Postgraduate Medicine, 1967.—"Intra-uterine Growth," Scottish Television and Tyne Tees Television: 31 October (1.15 p.m.), repeat 5 November (10.15 a.m.).

Mental Health Research Fund.—Public meeting, "The Promotion of Psychiatric Research," by Sir GEOFFREY VICKERS, 7 November, 5 p.m., Edward Lewis Theatre, Middlesex Hospital Medical School, London W.1.

St. Thomas's Hospital Medical School.—Old Students' Dinner, 10 November, 7 p.m. for 7.30 p.m., Savoy Hotel, London (entrance Victoria Embankment). Ladies welcome. Price of dinner, exclusive of drinks, £2 10s.

Chelmsford Medical Education and Research Trust.—Gynaecological seminar, 11 November, Chelmsford and Essex Hospital. Fee £1. Applications to St. John's Hospital, Chelmsford, Essex.

Royal Free Hospital Old Students' Association.—Clinical meeting, 16 November, 12.30 p.m. Hospital and Medical School Dinner, 7.15 p.m. for 7.45 p.m., Savoy Hotel. Details from Dr. J. R. M. GIBSON, 90 Bromley Common, Bromley, Kent.

Developmental Neurophysiology and E.E.G. in Paediatrics.—Course on problems of developmental neurophysiology and E.E.G. in paediatrics, 16-18 November, Hospital for Sick Children, Great Ormond Street, London W.C.1. Details from Dr. G. PAMPIGLIONE, department of clinical neurophysiology at the hospital.

Institute of Urology.—Week-end course on "Essentials of Urology," 17-19 November. For details see advertisement on p. xxxiii.

Biochemical Society.—Meeting, 18 November, Medical Research Council Laboratories, Carshalton. Programme includes colloquium on "Toxic Substances and Brain Metabolism." Further details from Executive Secretary, Biochemical Society, 7 Warwick Court, Holborn, London W.C.1.

St. John's Hospital, Lincoln.—Annual day conference on psychiatry, 19 November, 10.15 a.m.

Symposium on Carbenoxolone Sodium.—20 November, 9.40 a.m., Royal Society of Medicine, 1 Wimpole Street, London W.1. Open to all members of the profession. Tickets may be obtained, free of charge, from Mr. W. D. D. LEWIS, Berk Pharmaceuticals Ltd., Godalming, Surrey.

National Heart Hospital.—The St. Cyres Lecture, which was to have been given on 31 October at the Royal College of Physicians, will now take place.

Professor Ragnar Granit.

Professor Haldan Keffer Hartline.

Professor George Wald.

Societies and Lectures

For attending lectures marked ● a fee is charged and a ticket is required. Applications should be made first to the institution concerned.

Monday, 30 October

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.

INSTITUTE OF DISEASES OF THE CHEST.—6.15 p.m., Dr. J. H. Gough: Angiocardiography in Congenital Heart Disease.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Dr. V. Goodhill (Los Angeles): Some Crucial Problems in Case Selection and Surgical Technique in Tympanoplasty.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr. D. C. O. James: Pathology of Trauma—Blood Loss; 6.30 p.m., Dr. A. Bold: Aspects of Homeostasis—Calcium Metabolism.●

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Dr. N. A. Mitchison: Control of the Immune Response.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. Peter Bishop: Sex Chromosome Anomalies and Intersexual States.

Tuesday, 31 October

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. J. R. Tata: Hormonal Control of Protein Synthesis.

CHARTERHOUSE RHEUMATISM CLINIC.—At Royal Society of Medicine, 5.30 p.m., Gilbert Scott memorial lecture by Mr. G. K. McKee: The Development and Present Status of Total Prosthetic Replacement of the Hip Joint.

INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. I. Sarkany: Physiology of Itching.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 2 p.m., Mr. R. A. Tennent: Induction of Labour.●

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Professor G. Bras (West Indies University): Degenerative Diseases and Neoplasms as Influenced by Nutrition—an Experimental Study.

NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., clinical meeting by Dr. A. John.

ROYAL COLLEGE OF GENERAL PRACTITIONERS: SOUTH LONDON FACULTY.—At Board Room, King's College Hospital, 8.15 p.m., Dr. H. L'Etang: Great Men and Their Illnesses.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Professor A. K. Basu: Non-cirrhotic Portal Fibrosis with Portal Hypertension.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Professor R. B. Welbourn: Nutritional Aspects of Gastric Surgery.

ROYAL STATISTICAL SOCIETY: MEDICAL SECTION.—At Mansion Theatre, London School of Hygiene and Tropical Medicine, 5 p.m., Dr. M. C. Pike: Detection of Low Intensity Epidemics—an Extension of Knox's Model and Some Applications.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. E. A. Nieman: clinical demonstration.

Wednesday, 1 November

ASSURANCE MEDICAL SOCIETY.—At Medical Society of London, 5 p.m., Sir John Richardson: The Connective Tissue and its Disorders.

PSYCHOMETRIC SOCIETY: BRITISH REGION.—At Wellcome Building, Euston Road, London N.W., 2.30 p.m., Professor J. F. Scott: Investigation of a Psychological Syndrome by Multivariate Analysis.

BOOK GENERAL HOSPITAL.—8 p.m., Sir Terence Cawthorne: Vertigo—its Diagnosis and Management.

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.

INSTITUTE OF DENTAL SURGERY.—5 p.m., Wilkinson lecture by Sir John McMichael, F.R.S.: Science and Practice.

INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. R. W. Riddell: Diseases Caused by Fungi.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. W. D. W. Brooks: The Lungs in Systemic Disease.

OXFORD UNIVERSITY MEDICAL SCHOOL.—At Nuffield Maternity Home Lecture Theatre, Radcliffe Infirmary, 5 p.m., Professor T. Stamey (Stanford University): Reinfections of the Urinary Tract—Studies on the Portal of Entry.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., urology lecture by Mr. J. Cosbie Ross: The Neurogenic Bladder.

ROYAL FREE HOSPITAL.—5.15 p.m., Dr. G. L. Nardi (Boston): Surgery of Pancreatitis.

ROYAL MICROSCOPICAL SOCIETY.—At Edward Lewis Building, Middlesex Hospital Medical College, 5.30 p.m., Dr. A. Klug: Interpretation of Electron Microscope Images of Negatively Stained Biological Particles.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conferences by Dr. G. F. Joplin: Myelomatosis; Dr. J. G. Azzopardi: Amyloidosis. (2) 2 p.m., Renal Unit, urology seminar. (3) 2 p.m., Dr. A. C. Allison: Immunity Against Viruses and Tumours.

STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. V. E. Lloyd-Hart: clinical cases. (2) 6 p.m., Group Captain R. Mortimer: Malaria.

WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Professor J. G. Scadding: Sarcoidosis of the Lungs.

Thursday, 2 November

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Mr. D. P. Burkitt: A Study of Cancer Patterns in Africa.

DUNDEE UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Professor W. St. C. Symmers: Opportunistic Infections.

HONYMAN GILLESPIE LECTURE.—At Surgery Lecture Theatre, Edinburgh Royal Infirmary, 5 p.m., Professor G. Smith: Ischaemic Neuropathy associated with Atherosclerotic Disease in the Lower Limbs.

LONDON UNIVERSITY.—(1) At Royal Society of Medicine, 5 p.m., Semon lecture by Mr. D. H. Patey: Diseases and Disorders of the Salivary Glands in Relation to General Physiology and Pathology. (2) At Physiology Lecture Theatre, University College, 5.30 p.m., special university lecture in biophysics by Dr. B. Chance (Pennsylvania): Electron and Ion Transport in Mitochondrial Membranes.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—7 p.m., Dr. J. G. Dare: A Brief Survey of Australian Pharmacy.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Aris and Gale lecture by Mr. B. L. Whitaker: An Investigation into Factors Affecting the Blood Supply of the Descending Colon and Rectum.

ROYAL PHOTOGRAPHIC SOCIETY: MEDICAL GROUP.—7 p.m., informal discussion of problems in medical photography.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 4 p.m., Mr. P. Martin: Reconstructive Arterial Surgery. (2) 5 p.m., lecture on medical history by Dr. E. S. Clarke: Disease in Graeco-Roman Antiquity.

RUNWELL HOSPITAL.—At Wickford, Essex, 8 p.m., general medicine in relation to psychiatry by Dr. R. Brown: Cardiac Failure.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Mr. M. D. Cameron: Postoperative Management of Gynaecological Operations.

Friday, 3 November

KINGSTON-UPON-THAMES MEDICAL CENTRE.—8.15 p.m., clinicopathological conference by Dr. J. B. Harman.

NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 8.15 p.m., Professor S. Shuster: Skin and the Gut.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 10.15 a.m., Mr. F. B. Cockett, Mr. W. G. Fegan, Mr. Hugh Jones: Profile on Varicose Veins. (2) 4 p.m., Professor J. G. Scadding: Sarcoidosis—History and Definition.

WEST MIDDLESEX HOSPITAL.—4 p.m., Dr. C. Barnes: Non-toxaemic Hypertension in the Pregnant Woman.

Saturday, 4 November

PRINCESS ALEXANDRA HOSPITAL, ESSEX.—At lecture room, 2 p.m., symposium: Recent Advances in Rheumatic Diseases.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—9.30 a.m., anaesthetic teaching meeting: Mechanics of Ventilation during Anaesthesia.

Sunday, 5 November

EDGWARE POSTGRADUATE MEDICAL SOCIETY.—At Edgware General Hospital, Middx., 10.30 a.m., Dr. A. M. Joekes: Investigation of the Renal Tract.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on 18 October 1967, the following candidates who passed the requisite examinations were admitted Fellows:

M. M. A. A. Abdallah, M. M. Abdul-Hadi, C. B. T. Adams, M. L. Adiga, W. Ahmad, Maung Than Aung, S. C. Bagchi, K. Balasingham, B. Balgobin, S. C. Basu, A. Baxter, A. R. Bean, I. S. Begg, S. E. Benjamin, T. Bhaduri, W. M. Bowden, D. P. Byrnes, D. C. Carter, J. P. Chacko, J. Chamberlain, Chung Chun Chan, Wing Fook Chan, R. K. Chatfield, B. Chatterjee, A. B. Chaudhary, Z. U. Chaudhry, A. Constantinou, O. St. J. Da Costa, B. Dean, A. H. B. De Bono, A. N. Dey, T. S. Dogra, J. A. Dormandy, N. St. J. P. Dwyer, E. I. Efrong, H. W. Elcock, A. S. H. El-Ghorab, A. A. El Mannan, Marina D. Fakirbhai, G. Farago, G. H. Foster, J. W. Fowler, P. M. Fullman, J. N. Gangopadhyay, Siraj-Ul-Iqbal Z. Ghazali, G. S. Ghorpade, S. K. Ghoshal, E. S. Glen, H. F. Godfrey, G. Gordon, M. Abdel-Hamid, M. Gouda, W. E. G. Griffiths, A. Grover, A. J. Haddadin, Mg. M. T. Han, B. S. Heer, M. T. Hlaing, L. A. Holbrook, R. M. Honner, E. C. Horan, A. K. House, M. J. Hunter, Z. Huc, A. Hussain, Z. Iqbal, Md. A. Jalil, A. G. Jatoti, R. V. Jeffreys, W. G. Johnston, M. Kanagalingam, S. N. Kapoor, A. A. Kareim, P. Kakati, H. B. Kennedy, G. D. Kerr, I. A. Khan, R. C. Khosla, L. Krogh, R. B. Lea, Yiu-Ting Lee, Chun-Kuen Leung, A. B. Lockhart, F. I. Low-A-Chee, W. Lloyd-Jones, B. St. C. McCormick, I. J. A. Macfarlane, A. B. MacGregor, S. T. D. McKelvey, R. D. W. McLean, A. Mahmud, A. Majekodunmi, S. P. Malhotra, G. S. Mangat, C. E. Marshall, J. P. Matthews, D. P. L. May, G. M. Memon, P. B. M. Menon, A. H. Mike, R. N. Mohapatra, W. B. Molloy, S. H. Mong, M. L. Mulcahy, A. A. Nada, G. Neil-Dwyer, A. N. Nicolaides, K. N. Oji, Saw Young Ong, P. J. O'Rourke, G. A. A. Oyemade, B. J. Parakh, D. J. Parker, A. Patel, S. P. Payne, T. Y. Pemba, C. N. Pillay, B. Prakash, K. Prasad, S. P. Puri, J. M. Quilter, M. Rahman, E. W. Ramsey, W. R. Roney, P. B. Roy, E. A. Saad, I. Scott-Findlay, Pramila B. Sehgal, D. K. Sen, H. J. Shah, B. Shahi, M. Shamm, U. C. Sharma, J. M. Shennan, M. A. T. Siddique, D. C. Simpson, I. S. Smith, V. I. Sreenivas, T. E. Steven, Mrudula A. Talwalkar, P. A. Tan, J. F. Tattersfield, J. T. Taylor, N. P. Tendolkar, H. K. D. Thakore, M. Thambirajah, I. W. Thomas, Marjorie P. Thomas, P. Thompson, O. N. Tikki, G. S. Tucker, A. P. Tynan, D. W. Walters, J. M. Watts, J. H. Wheeler, J. H. White, E. Whitehead, P. J. R. Zelas.

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

BRITISH JOURNAL OF PREVENTIVE AND SOCIAL MEDICINE

Contents of the October issue are as follows:

- Problems of Emergency Admissions to London Hospitals. M. D. Warren, J. Cooper, and J. L. Warren.
 Inter-American Investigation of Mortality. R. C. Wofinden and P. N. Dixon.
 Heights and Weights of Adults in Rural and Industrial Areas of South Wales. M. T. Ashcroft, H. G. Lovell, W. E. Miall, and F. Moore.
 Assessment of Habitual Physical Activity apart from Occupation. S. Yasin, M. R. Alderson, J. W. Marr, D. C. Pattison, and J. N. Morris.
 Incidence on Menarcheal Age in Girls in a Welsh College. D. F. Roberts and T. C. Dann.
 Changes in the Incidence of Anencephalus. I. Leck and S. C. Rogers.
 Cancer and Bronchitis in Relation to Cigarette Smoking and Fuel Consumption in Twenty Countries. P. Stocks.
 1967.

Volume 21, No. 4. Yearly subscription (4 numbers) £3 3s., abroad £3 10s.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitology*, London W.C.1. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY 4 NOVEMBER 1967

Pointers

Intensive Care: Description of organization and results in a respiratory unit set up after a preliminary survey to assess the need for such a unit in Glasgow (p. 255).

Visuo-motor Handicap: Poor school performance in spite of average I.Q. in a number of healthy children explained by visuo-motor defect. Some of these children had a history of perinatal abnormality (p. 259).

Aspirin and Chronic Urticaria: Aspirin-containing drugs caused exacerbation in some patients with chronic urticaria. This action may be due to enhancement of effect of histamine in the skin (p. 262).

Salicylates in Rheumatoid Arthritis: Trial to demonstrate clinical assessment of anti-inflammatory properties of rapidly acting drugs shows that high dosage of salicylates produced measurable reduction in joint size (p. 264). Leader at p. 251.

Relief from Angina: Comparison of aerosol and sublingual administration of glyceryl trinitrate in a double blind trial showed tablets still to be the treatment of choice (p. 268). Leader this page.

Treatment of Septicaemia: Intravascular coagulation caused by *Cl. perfringens* successfully treated by exchange transfusion and heparin (p. 271).

Topical Corticosteroids: Comparison of commonly used preparations shows betamethasone 17-valerate ointment to be significantly better than fluocortolone in patients with eczema and psoriasis (p. 275).

Case Reports: Charcot joints in early adolescence (p. 277); Coarctation of aorta complicated by subarachnoid haemorrhage (p. 278); True heartburn (p. 279).

Dyspepsia: Diagnosis, medical management, and indications for surgery of duodenal ulcer (p. 281).

Is There an Alternative? Review of B.M.J. booklet on the Health Service (p. 285).

Obstetric Services: National postal survey of general-practitioner maternity units reveals that almost half of them are more than ten miles from consultant units, and lack formal arrangements for consultant visiting (p. 287).

Council: Report of meeting (*Supplement*, p. 29).

Central Committee for Hospital Medical Services: Report (*Supplement*, p. 36).

Surrey Public Health Appointment: Call for inquiry (*Supplement*, p. 41).

Treatment of Myocardial Ischaemia

Anginal pain is felt when the myocardium's demand for oxygen outstrips the available blood supply. Relief stems from improvement in the flow of coronary blood or from reduction in cardiac work.

Until recently the rationale of anti-anginal drugs has been to improve blood flow, but observation of the sort of disease commonly present at necropsy suggests that attempts at pharmacological coronary dilatation must be futile. Though dilatation of healthy parts of the main coronary arteries can be observed during cine-angiography,¹ no coincident improvement in blood flow has been detected.² Indeed, dilatation of healthy arteries could well divert blood away from ischaemic areas supplied by the more rigid diseased vessels.

The undoubted benefits of nitrites in the treatment of angina are almost certainly owed to peripheral rather than coronary vasodilatation, a reduction in cardiac size and work following a decrease in the venous return and arterial pressure.^{3,4} When taken before pain-provoking exercise, glyceryl trinitrate both prevents the pain and reduces the electrocardiographic changes of ischaemia. But it has not been shown to be effective in relieving established attacks,⁵ though widely used for this purpose. Apparent benefit from it in those circumstances may result simply from the expectation of relief, and indeed the brevity of the ordinary attack makes it difficult to assess the effect of any anti-anginal drug except in prophylaxis. Natural improvement also frequently occurs and makes the efficacy of therapy still harder to judge.

A different approach to treatment came with the introduction of β -adrenergic blocking drugs such as propranolol (Inderal), which block the cardiac actions of adrenaline.⁶ The demand of the myocardium for oxygen is roughly proportional to the heart rate,⁷ and probably the most important benefit from propranolol lies in the prevention of tachycardia during exertion or emotion.⁸ β -Adrenergic blockade also reduces the wastage of oxygen that can result from an adrenaline-induced increase in vigour of contraction. Coronary flow is facilitated by a longer diastolic filling period, and anxiety is relieved through the patient's awareness of a slower heart beat. Other lesser benefits may be a slight fall in blood pressure and the suppression of exercise-induced ventricular ectopic beats.

Propranolol can be of great therapeutic value in preventing angina provided a sufficiently high dose is prescribed and the contraindications to its use are observed. Less than 150 mg. of the drug daily in divided doses is rarely of benefit and even 250 mg. may be needed. Left ventricular failure is a complete contraindication, and signs of incipient failure should be carefully sought while the dose is being gradually increased. Removal of the support that the patient derives from adrenaline is the reason why patients with heart failure are extremely sensitive even to small doses, why the drug is largely contraindicated in cardiac infarction, and why overt heart failure may be precipitated by its use in patients with impaired myocardial performance.

No. 5574, page

By slowing the heart, not the man, β -adrenergic blockade has finally rendered thyroid ablation obsolete. Many other drugs are of value, but they act mainly as a sedative or even a placebo. Delayed-release glyceryl trinitrate tablets can be an effective prophylactic over a 6- to 8-hour period, but occasionally cause sustained headache and postural hypotension as a direct result of the nitrite action. "Long-acting nitrites" such as pentaerythritol tetranitrate on the other hand never achieve a pharmacologically sufficient level of nitrite in the blood. Drs. G. Sandler and G. A. Clayton, writing in the *B.M.J.* this week at page 268, have assessed an aerosol preparation of glyceryl trinitrate by an excellent double-blind trial but found it ineffective. Sustained-release tablets may be beneficial, and a few patients still prefer amyl nitrite inhalation. Monoamine oxidase inhibitors had a vogue, but their serious toxic effects and dangers preclude their use in angina, especially as any benefit they conferred was largely through their euphoriant action.

The physician has four lines of treatment in angina. The first two are general ones—to increase bodily efficiency and to try to prevent progression of the arterial disease. Obesity, hypotension, or diabetes is corrected.^{9,10} Restriction of dietary fat and the taking of clofibrate (Atromid S)¹¹ are advised only if the levels of serum cholesterol or triglycerides are abnormal. Smoking is to be condemned but alcohol allowed, and regular physical exercise is encouraged. A programme of graduated exercise is beneficial,¹² but whether through the psychology of group therapy, better general fitness, or an actual improvement in myocardial perfusion is not yet known. Whatever the explanation, there is no doubt that the patient with angina benefits greatly from this recently changed attitude towards exercise.

The mainstay of drug therapy is still glyceryl trinitrate supported by propranolol if further relief is needed. But, if angina remains recalcitrant, surgical revascularization should be considered. Before a decision can be made, coronary angiography is mandatory.¹³ It has now been shown that implantation of an internal mammary artery can in time revascularize an ischaemic but viable area of myocardium.¹⁴ These implants seem to "take" only in an area whose need for better perfusion can be demonstrated by finding delayed flow through a narrowed segment of artery or retrograde flow through collaterals from the opposite main vessel, and in which, preferably, new collateral vessels are already growing.

Reconstruction of the lumen of the left coronary artery or its main branches has been found to carry a high mortality, but the right coronary lumen has been successfully restored at low risk by reroofing it with a pericardial patch.¹⁵

In the last few years great progress has been made in the palliation although not in the prevention of coronary disease. Patients with angina tend to become emotional and introspective because their symptoms have so often been only temporarily alleviated by the hope of help from a new drug or a new physician. They need time, explanation, confidence, and a plan. These they can and should be given.

Computers in Medicine

The first electronic computer was produced in the United States in 1946. Immediately the speed of calculation was increased a thousandfold. Today the computer is a thousand times faster.

Computers as well as calculating can store and recall information, and unlike their human creators they do not forget. They can perform even more complex operations and can indeed operate any set of rules on any set of symbols. If the symbols are numbers and the rules are those of arithmetic the computer will calculate. If the symbols represent the words of two languages and the rules specify their grammar the computer will translate. The problem is to define the "grammar" to enable the computer to "translate." It is because the grammar of arithmetic is relatively straightforward that calculation by computer was quickly established. If the grammar for classifying electrocardiograms, electroencephalograms, or electromyograms was as simple the computer would be equally efficient in their interpretation. But its relative inefficiency at present is not the fault of the computer. The difficulty lies in preparing the programme for it. A diagnosis is more easily reached than explained, and the steps taken must be analysed before a programme can be prepared for a computer.

Even the most powerful computer can originate nothing. It can only carry out a sequence of operations and choose between alternative sequences when the need for this has been foreseen. Essentially it consists of a store, a control unit, an input unit, and an output unit. In the store are placed both the data to be worked on and the programme of instructions, specifying precisely what has to be done. Alphabetical and numerical data are stored electronically, so that on the mere press of a button in the control unit they can be processed by a programme of instructions also stored electronically. This function is called "automatic data processing." The output channel then reconverts the electrical impulses back into punched-paper tape, which is fed into a teleprinter-interpreter combination. This deciphers each digit in turn and types it out automatically on an electric typewriter. Both the teleprinter used for preparing input tapes and the teleprinter-interpreter combination are "off-line." This means they are not directly controlled by the computer and can therefore be hundreds of miles away. Devices such as the input reader and the output punch are directly controlled by the computer and are therefore "on-line" devices.

The enormous potential of computers in the medical and biological fields is only beginning to be appreciated. These

machines arrange vaccination and immunization programmes of some public health departments, and their vast possibilities in the field of biochemical laboratory measurements are becoming apparent. Autoanalytical methods are well developed for sampling blood plasma for electrolytes and are in use in most hospital laboratories. The results from these instruments are produced on automatic pen-recorded charts. Data from the charts can be inserted directly into the computer by a device that measures the height of the curves at intervals and converts each height into a coded row of holes on continuous paper tape. If a suitable programme is prepared the computer will then analyse and record the results. If previous biochemical records of the patient have been stored in the computer they can then be sought and retrieved from the store. With the number of hospital biochemical investigations doubling every five years such automation must obviously be exploited to the full.

Computers are playing a part in planning radiation treatment. The delivery of the optimum highest dosage to tumours while subjecting normal tissues to the minimum dose requires much work in the planning of individual treatments. An accurate assessment of differing absorption in fat, air, and bone demands much tedious and time-consuming work. By developing a computer programme using the knowledge of the most experienced physicist it is possible for less-informed junior staff to produce a plan of treatment.

The assistance of computers has, however, never been more essential in medical practice than in the investigation and diagnosis of cardiovascular disease. The assessment of its role in cardiovascular investigation by S. H. Taylor and his colleagues in a recent issue of the *British Heart Journal* is therefore timely.¹ The applications of computers include epidemiological studies, E.C.G. diagnosis, cardiovascular diagnostic investigations, and the continuous monitoring of patients with severe myocardial infarction. Indicator-dilution techniques for measuring cardiac outputs have been so automated that dilution curves can be produced by automatic injection and the sampling of arterial blood at any desired frequency and for any length of time. The information produced by these methods is overwhelming, for each hour spent in investigating provides more than 80 hours of work by skilled staff in assessing the results. This is not only time-consuming but intellectual imprisonment. Computer-assisted analysis offers an obvious solution. The curve from the automatic pen-recorded charts of cardiac output can be prepared for insertion into the computer in a similar way to biochemical autoanalytical data.

Taylor and his colleagues have been in the forefront of the application of computer programmes to cardiovascular problems. They have prepared computer programmes for cardiovascular investigations and have surmounted many of the problems presented by the computer's ineptitude at pattern recognition. They have assessed the precision with which three computers measure the cardiac output in man and have determined their usefulness in cases of abnormalities of cardiac rhythm and valvular disease. As well as showing how cardiac investigations may be advanced they have given an important lead in surmounting the many difficulties caused by artifacts in the tracings. Their work is a reminder that the potential of computers in the medical field is still largely untapped and it should stimulate the application of them to other branches of medicine.

Testing Drugs for Rheumatoid Arthritis

The medical treatment of rheumatoid arthritis is based on measures to reduce the pain, heat, redness, swelling, and inflammation. The pharmaceutical industry devotes vast resources to discovering new drugs for this purpose. Promising compounds are screened by animal tests. Those few which pass have still to be tested in man, since there is no guarantee that ability to check experimental inflammation in the rat implies ability to check rheumatoid inflammation in the human joint. But more effective anti-inflammatory drugs are needed, for the preparations at present available have many deficiencies, and there are always patients who fail to respond to one drug and yet respond to another. Any effective new preparation, even if not specially remarkable in itself, increases the pool of reserve drugs which can be brought into play.

Facilities for testing anti-inflammatory drugs in human disease are not easily found, nor are the doctors with both the will and the skill to do the task. Thus clinical testing is, to borrow the pharmacologists' jargon, the "rate-limiting factor" in the availability of new anti-inflammatory drugs. For this reason the paper by Drs. P. L. Boardman and F. Dudley Hart at page 264 of the *B.M.J.* this week is of practical importance in that it describes methods which are simple, reliable, and reproducible for assessing anti-inflammatory drugs in rheumatoid arthritis. These methods can be used in outpatient departments in any hospital or rheumatism clinic. They consist in a short-term, controlled trial, with alternate or random allocation of patients to an initial treatment group and then crossing-over to the other group. Measurements of heat and redness in rheumatoid arthritis being unreliable, Boardman and Hart concentrated their attention on measurements of swelling and function. They first used jewellers' rings to measure swelling in the finger 16 years ago.¹ But they have been able to show that a small instrument which measures the circumference of the joint directly is equally reliable and much more convenient for routine use. Strength of grip is another method long used for measuring hand function. A modified sphygmomanometer cuff of prescribed dimensions is inflated and connected to a mercury manometer. In practice strength of grip reflects both pain and structural dysfunction, but chiefly pain. Provided these methods are used at precisely the same time of day and the same time after giving the drug, they are now so reliable and reproducible that they deserve internationally agreed standardization.

Boardman and Hart found—as others have done—that placebos may apparently be followed both by "toxic" reactions and by apparent therapeutic benefit. Doctors untrained in mathematics used to boggle at the statistics involved in trials. Nowadays the path is eased by the technique of sequential analysis² and the now familiar "pair of trousers" charts,³ by which preferences between paired observations can be entered on the chart and the trial stopped as soon as a result unlikely to have happened by chance has been obtained. Using such methods, Boardman and Hart show that prednisolone has an undoubted anti-inflammatory action, that paracetamol has little, if any, anti-inflammatory action, and that salicylate in low dosage can relieve the pain of inflammation

but that high dosage is needed to affect the swelling. Their paper exemplifies methods which clinicians could use more widely for the clinical testing of potentially useful new anti-inflammatory drugs.

No Need for Change?

The Minister of Health in H.M. (67) 58 has told members of hospital boards and committees that he does not accept the need for fundamental changes in methods of training nurses proposed by the Royal College of Nursing in its publication *A Reform of Nursing Education*.^{1 2} The Minister believes that improvements can be produced by the provision of more tutors or better use of those available, by better selection of students and possibly the streaming of entrants, and by careful attention to the principles of student training.

Nurse administrators will read the form of self-examination suggested for their use somewhat glumly. Nothing is suggested that they have not often thought about before, but perhaps committees will listen with more attention to the Minister than they have to nurse advisers. In addition, hospitals will now be required to give returns of their student wastage, and, while this may be thought to amount to examining the stable door after the horse has bolted, the information ought to be available from all training schools.

The last section of the memorandum ends with suggestions for experimental schemes of nurse training. Hitherto, training schools have submitted such schemes to the General Nursing Council, which has sent those approved to the Ministry for ratification, and the Council has had many such schemes to consider. The Minister's list contains one new idea—that students might attend colleges of further education, presumably on a day-release basis, for "liberal studies."

At the same time as H.M. (67) 58 was published the General Nursing Council received from the students of a nurse-training school a letter which throws doubts on the validity of the Minister's belief that all is fundamentally well in nursing schools. Here is an extract:

"We wonder whether any of you know under what sort of conditions we are working here due to chronic shortage of staff. . . . This hospital seems to be staffed only by student nurses and a few sisters. The student nurses do not get any teaching experience on the ward due to the shortage of time and trained staff. One leaves a ward after three months' drudgery without ever being taught anything whatsoever. Does one attempt to do a procedure properly, we are very often told there is not time to do a sterile procedure. . . . Still exhausted from the previous day, we often find ourselves alone on the ward, dishing out breakfast for 28 patients, feeding many of them as well. . . . Night duty follows a very similar pattern. One is put alone in charge of a 28-patient ward without previous experience of night duty, giving out drugs, or general supervision of patients."

The full text was published in the *Nursing Times*³ recently and a copy was sent to the Minister. It reminds us that nobody and no organization concerned with nurse training can be satisfied with the present position.

Modernizing Hospital Medicine

One of the more depressing features of British medicine for those who believe in the N.H.S. is the antagonism between the profession and the Health Ministers. It is, therefore, all the more encouraging this week to find representatives of the two sides agreeing on the major faults in the organization of medical work in the hospital service. Just as welcome are their suggestions for reform, for these are both radical and realistic.

A joint working party of doctors and hospital administrators was set up by the Secretary of State for Scotland in 1965 with instructions to look for ways of improving efficiency in the hospital service. A little later a similar body was set up by the Ministry of Health and the Joint Consultants' Committee. Their first reports^{1 2} are summarized at page 291 of this week's *B.M.J.*

Fundamental to future planning for the hospital service is the knowledge that there are too few doctors and that there is no prospect of enough for at least ten years. So doctors must be used more efficiently, and their morale must be improved if they are not to emigrate. The Scottish report accepts that the discrepancy between the number of registrars and the number of potential consultant vacancies is responsible for much anxiety among junior staff, and recommends that numbers in the registrar grade should be reduced to the minimum which would allow for natural wastage and competition. The long-term solution to much of the discontent lies at this intermediate level of hospital work, where there is need for greater integration with general practice. The Scottish Working Party believes that much of the work could be done by family doctors if they could be brought into the hospitals as, say, part-time medical assistants. The report recognizes that expansion of the medical assistant grade has dangers, particularly the risk of consultant responsibility being carried by assistants—and it accepts that the present sessional rates of pay are not good enough to attract general practitioners. Such an appreciation of realities is welcome, as is the Working Party's conclusion that "these difficulties must be resolved however intractable they may seem."

Both reports agree that the tradition in hospitals of consultants having a fixed allocation of beds is inefficient and out of date. Both propose that hospitals should change over to a divisional system of staffing, similar to that widely used in North America. A division would consist of all the doctors working in one specialty—or in several specialties if they are linked in their functions. Chairmen of divisions would be appointed, and a committee formed of these chairmen or their representatives. Outside Scotland the chairman of this committee would hold a post roughly equivalent to the American chief of staff; in Scotland the position of medical superintendent would be retained.

These changes should lead to a greater exchange of ideas between medical staff, as well as promoting the more efficient use of beds, staff, and equipment. The danger is that a doctor's freedom to treat his patients as he thinks best may be eroded by pressures for the adoption of uniform regimens of management. Neither report even hints at the introduction of sanctions that could be used to force the nonconformist into obedience, though these do exist in certain American hospitals. The Scottish report states, "While we do not wish to depart from the principle that each

² *First Report of the Joint Working Party on the Organization of Medical Work in Hospitals*, 1967. H.M.S.O. Price 2s. 9d.

consultant is personally responsible for his own patients, we see great value in the results of clinical work being examined on a group basis." Later in the report there are proposals for the introduction into Scotland of the "medical audit" and for alternatives to traditional systems for hospital care.

All these proposals will not easily find general acceptance. But if British medicine is to maintain its reputation internationally then modern methods of organization and assessment must be introduced. Clinicians must ensure that the new methods do not reduce their proper clinical freedom—the traditional duty of each doctor to treat his patients in the way he believes to be best.

Operation for Parkinsonism

At the beginning of this century Robert Clarke designed a machine, modifications of which have revolutionized the treatment of Parkinson's disease. Clarke's patent specification¹ clearly defined the principle of stereotaxis: "This invention relates to what may be termed stereotaxic surgical apparatus for use in performing operations within the cranium of living human beings . . . (it) is designed to enable a so-called probe . . . to reach, with absolute precision and by the shortest path, any predetermined point within the cranium through a comparatively small opening in the wall of the latter, the primary object being to obviate the necessity of extensively laying open or partially dissecting the head and removing considerable portions of the cranial contents in order to gain access to the exact spot whereat the actual operation is required to be carried out."

Clarke worked in association with Sir Victor Horsley, but they used the machine exclusively for work in animals. It was not until 1950 that E. A. Spiegel and H. T. Wycis reported the use of stereotaxis in man at a meeting of the American Neurological Association. Using a modified Clarke's stereotaxic apparatus,² they had succeeded in abolishing choreoathetotic movements by means of electro-coagulation of the globus pallidus of the side opposite to the involuntary movements. Spiegel and Wycis³ later found they could improve tremor and rigidity in Parkinson's disease by the same operation; but technical difficulties arose from the great variation in man between the external landmarks of the skull and the targets in the brain. J. Talairach and his colleagues⁴ overcame this problem by using ventriculography to relate cerebral structures to the target areas. Experience of many workers has shown that the nucleus ventrolateralis and the nucleus ventroposterior lateralis of the thalamus are better targets for the treatment of Parkinsonism than the globus pallidus.

Most patients with Parkinson's disease have a good chance of worthwhile relief of symptoms if certain conditions are fulfilled.⁵ There must be no mental deterioration and the Parkinsonism must not be so far advanced that the patient is entirely dependent on the help of others. The stereotaxic apparatus should be capable of finding the selected target accurately to within one millimetre. The passage of the electrode or cannula to the target should be made through a "silent" part of the cerebrum. Patients with bilateral manifestations of the disease can be successfully treated provided

that the smallest therapeutic lesion necessary to produce the desired effect is made on each side and that an interval of at least six months is allowed between treatment of the first and second sides. Individual variation in the position of the thalamic nuclei should be taken into account.

The most important factor other than technical considerations which affects the result of surgical treatment is the pattern of the disease. Patients with long-standing unilateral symptoms are almost certain to obtain complete relief, whereas patients who are completely incapacitated by the disease have little to gain. Between these two extremes are ambulant patients with bilateral symptoms, who can be offered substantial benefit from bilateral stereotaxic thalamotomy. Severe ataxia, dysarthria, and involuntary salivation are resistant to treatment.

Age alone does not appear to affect the result of operation—L. C. Oliver⁵ reported several patients over the age of 70 who had been treated successfully. A long history of slight or moderate disability is not necessarily an adverse factor; indeed it usually indicates slowly progressive disease and tends to favour a good and lasting result. This is true also of postencephalitic Parkinsonism, in which oculogyric crises are abolished or their frequency reduced in about a third of the patients. Finally, though nothing can be done at present to arrest the degenerative process underlying Parkinson's disease, follow-up of patients after operation seems to indicate that the development of further symptoms may be arrested by thalamotomy.

Complications of Vaccination

Vaccinia is much the commonest iatrogenic disease. Between 1951 and 1960 there were over 5 million cases in England and Wales,¹ though fortunately the great majority of them were mild and uncomplicated. Most of the patients, moreover, were immunologically better off after than before their illness. The argument is sometimes put forward that a person has little advantage in possessing antibodies against an infection he is unlikely to encounter, and it gains some support from the fact that, though there may be no harm in having a few reserve antibodies, in acquiring them some patients die, some pass through long, worrying illnesses, and some suffer enough discomfort to interfere with work and other pursuits. Vaccinia is a virus disease. If the infection were acquired naturally, virologists would be jostling for elbow room at their benches in their eagerness to isolate the virus and produce a vaccine against the disease. But with vaccinia the tables are turned, and it is the epidemiologists and the administrators who are left to control this troublesome infection.

The complications of vaccinia have been recently reviewed in Great Britain¹ and the U.S.A.² While there are several points of difference in the two studies, which might be related to such widely different factors as the strain of vaccine virus and the accuracy of reported figures, there are two important points of agreement. These are, firstly, that children under 1 year old suffer most complications, and, secondly, that many of the complications are preventable. In the British series¹ of over 5 million cases there were four deaths from eczema vaccinatum and seven from vaccinia gangrenosa, all in children under 1 year old; there were 22 deaths from postvaccinal encephalitis, 16 of them in children under 1 year old. In the American series of over 14 million cases the frequency of complications in children under 1 year was two or three times

¹ Clarke, R., Patent No. 22,455, 1912. London.

² Spiegel, E. A., Wycis, H. T., Marks, M., and Lee, A. J., *Science*, 1947, 106, 349.

³ ———, *Stereencephalotomy*, 1962, vol. 2. New York.

⁴ Talairach, J., de Ajuriaguerra, J., and David, M., *Presse méd.*, 1952, 60, 605.

⁵ Oliver, L. C., *Parkinson's Disease*, 1967. London.

higher than in any other age group, though it must be noted that no child under 1 died. There were 12 cases of post-vaccinial encephalitis, but only one in the first year of life, and all five children who died were aged between 1 and 14 years. There were two other deaths from eczema vaccinatum, both in children in the 1-4-years-old age group. The odd differences between the rates in the two series, especially for post-vaccinial encephalitis, cannot be explained, but such anomalies have been observed before. The figures collected by the Vaccination Committee of 1926 showed a preponderance of cases of postvaccinial encephalitis and of deaths in children of school age,³ whereas the figures reported to the Ministry of Health during 1951 to 1960 showed that both cases and deaths were much more frequent in the first year of life. Reporting of cases was probably incomplete in both periods and comparisons are therefore difficult, but the policy of recommending vaccination in the second rather than the first year of life is based on the more recent figures.

As to the prevention of complications, certain points are clear. Vaccinia is an infectious condition and infection can be readily transferred from the vaccination site to other parts of the body. This is the commonest cause of most cases diagnosed as generalized vaccinia. It is rarely a serious complication, but it should be preventable by careful hygiene. Transfer to another person is less common but may be more dangerous: 54 cases, including the two fatal cases, of eczema vaccinatum in the American series were caused in this way. A child with eczema must be protected rigorously against accidental vaccination from contact with a recently vaccinated person. Vaccination of a child with florid eczema is a hazardous operation and should be undertaken only on dangerous exposure to smallpox and under cover of hyper-immune vaccinia gamma globulin and possibly *N*-methylisatin beta-thiosemicarbazone. When the eczematous state is past or latent the risk is less, and such patients have often been vaccinated without trouble. This is true also of patients with asthma and other allergic disorders, but it is safer not to vaccinate such patients unless it is unavoidably necessary. Except during outbreaks, immigration authorities will usually accept a medical certificate stating the facts. Any immunological defect such as hypogammaglobulinaemia is another contraindication to vaccination,⁴ and a history of recurring infections during early infancy should lead the physician to obtain an analysis of blood globulins before he undertakes vaccination. Corticosteroids are known to affect immune responses, so that vaccination should be avoided for patients on long-term treatment with these substances, or, if it must be carried out, hyperimmune gamma globulin should be given beforehand. It is undesirable to vaccinate a patient with a skin infection. There is a very small risk of causing abortion by vaccinating women in the early months of pregnancy⁵ and of producing vaccinia in the foetus by doing it in the late months.⁶⁻⁸ Whatever the national policy about routine vaccination of a country, many of the complications can be avoided by excluding from the programme those patients in whom there is a contraindication to the treatment.

Reform Needed

The absence of any successful appeal from a finding of the General Medical Council since the creation of the right of appeal to the Judicial Committee of the Privy Council in 1950 at first sight may appear to be a remarkable compliment to the G.M.C. But criticisms made by the Privy Council from time to time show the G.M.C. to be no less fallible or human than other judges. The lack of any successful appeal is really a reflection on the machinery provided for disciplinary proceedings by the Medical Act, 1956, and by statutory instrument. That machinery has been much criticized, and many of the criticisms have been forcefully stated recently by J. L. Taylor.¹

The results of the G.M.C.'s lack of jurisdiction to impose any sentence other than erasure from the *Medical Register* are far-reaching. To reduce the injustice that might result from a choice restricted to erasure or acquittal the device of postponing judgement or finding has been developed. This produces something like a sentence of being put on probation, but, as Taylor points out, the practitioner not only has to be of good behaviour during the period of probation but has to prove his good behaviour by providing references. It would be in the public interest, and merciful to the practitioner, if the G.M.C. had the power in appropriate cases to impose a fine or a period of suspension from practice. When the draughtsman of the Medical Act 1956 formulated the right of appeal in section 36 he accorded this right of appeal only to the practitioner whose name is ordered to be erased from the *Register*. In all other cases the practitioner either stands acquitted or he is told that no final judgement has been passed upon him. Though it is logically undesirable to grant a right of appeal from a decision which in form has not been made, postponement of judgement is in truth a finding of guilt, and justice demands that there should be an immediate right of appeal. The whole device of postponing judgement is a denial of justice which ought not to be tolerated. It is a basic requirement of justice that courts and tribunals should not only hear but also determine the issues before them as speedily as may be, and publish their determination forthwith.

In addition to a greater variety of punishments Taylor would like to see some machinery for imposing suspension without stigma when a practitioner's health (usually mental health) makes this desirable. Taylor also points out that in some circumstances a practitioner faces charges without being told the details of what is alleged against him. There is a good case for a requirement that a "circumstantial letter" be sent to every practitioner who is charged before the G.M.C.

It is not only in its machinery that the G.M.C. is hampered. The whole concept of "infamous conduct in any professional respect" requires deep examination. It is questionable whether it is desirable to try to separate the professional life of a professional man from his private conduct. A charge of "conduct unbecoming a medical practitioner" would enable the G.M.C. to make a more flexible approach to complaints against practitioners, though it may be that such flexibility would prove too severe upon practitioners. The esteem in which members of the G.M.C. are held contrasts markedly with criticisms of the procedure and rules of the disciplinary process of the profession. The whole subject is appropriate for examination by the Law Commissioners.

Brit. med. J., 1967, 4, 255-259

Each hospital community setting out to organize a system of progressive patient care, including an intensive care area, must attempt as a preliminary step to answer certain general questions. For example: How many beds out of the total available in the hospital will be required for intensive care of the most seriously ill patients? How long will these patients occupy the available beds? What will be the distribution of patients according to age? What mortality rate may be expected? In an attempt to answer these questions for the Glasgow Royal Infirmary a survey of patients in the hospital was carried out between July 1963 and January 1964. For the first three months the entire hospital population was assessed, and for the second three months the survey was confined to two general medical units and two general surgical units. This latter selective assessment made possible a closer scrutiny of the individual patients involved. In all, 280 patients were included, and the criteria for selection for the hypothetical intensive care area were taken to be: (a) if the patient required an individual nurse for any or all of the time, or (b) if any specific therapy requiring continual observation was necessary. The patients thus selected were arbitrarily classified according to whether the main problem was respiratory, cardiovascular, metabolic-biochemical, traumatic, etc.

Tables I and II give the results of the investigation in so far as age groups and bed occupancy were concerned. It was found that approximately 4% of the total bed complement

TABLE I.—Distribution of Intensive Care Patients by Age Groups

Report	Age Group (Years)								
	0-10	11-20	21-30	31-40	41-50	51-60	61-70	71-80	81-90
Interim*	10	10	14	27	38	36	29	17	7
Final†	3	2	9	10	14	20	22	8	4

* Interim report represents a hospital-wide survey of three months' duration.
† Final report represents a three-months study of four selected units.

TABLE II.—Distribution of Patients by Number of Days of Intensive Care

Report	Duration of Intensive Care (Days)				
	1-2	3-5	6-10	11-20	Over 20
Interim	41	84	41	18	4
Final	19	42	19	9	3

of the hospital would be required for all intensive care purposes. For the Glasgow Royal Infirmary this would be about 40 beds.

The mortality in patients thought to require intensive care was found to be 19%. The overall hospital mortality during this six-month period was 4.2% for the first three months and 6.1% for the second three months.

Respiratory Intensive Care Unit

Against this background of general data acquired from the prospective study, it is of interest to examine in detail the actual experience in one of the intensive care units in the Glasgow Royal Infirmary—namely, the respiratory intensive care unit. In October 1962 a "pilot" four-bed unit for the treatment of acute respiratory emergencies, both surgical and medical in origin, was opened. This unit was converted from a six-bed side-ward, and despite the reduction in bed numbers was far from ideal so far as floor space was concerned, and too small to enable isolation cubicles to be constructed.

This paper comprises an analysis and discussion of 488 patients treated over a period of four years. Table III summarizes these results, classifying the patients under the headings indicating the primary cause of the respiratory problem. The number of patients requiring temporary tracheal intubation or tracheostomy and mechanical assistance to ventilation are shown. The average length of stay in the intensive care unit for each group is also given.

TABLE III.—Analysis of Patients Treated in the First Four Years in the Respiratory Intensive Care Unit

Condition	Cases		Requiring E.T.T. or Tracheostomy		Requiring I.P.P.V.		Average Stay in Unit (Days)
	No.	%	No.	%	No.	%	
Traumatic ..	195	39.95	108	55.4	52	26.6	10.3

Traumatic Respiratory Problems

In Table IV the traumatic group of respiratory problems is divided into those patients suffering from the "crushed chest" syndrome (75 patients), multiple injuries with a respiratory/metabolic upset (73 patients), and severe head injuries requiring special measures to maintain a clear airway and adequate alveolar ventilation (47 patients). The overall survival rate in these severely ill patients was 58.9, the lowest

TABLE IV.—Analysis of Traumatic Group of Respiratory Problems

	Cases	Survivals
Chest injuries ..	75	53 (70.6%)
Multiple ..	73	44 (60.3%)
Head ..	47	18 (38.3%)
Total ..	195	115 (58.9%)

survival rate being in the grave head injuries. Those patients who suffered severe injuries to the thoracic cage and lungs presented the greatest challenge to the staff of the intensive care unit. This type of injury has in the past always carried a high mortality. The method of treatment employed in the Glasgow Royal Infirmary has been reported elsewhere (Reid and Baird, 1965; Campbell, 1966).

Postoperative Respiratory Problems

Those patients who presented with significant postoperative respiratory difficulties, whether following elective or emergency surgery, were treated in the intensive care unit. As there was a shortage of 24-hour recovery facilities, inevitably a proportion of the patients in this group were admitted to the respiratory unit only for short-term postoperative observation and therapy. Nevertheless, the average length of stay was 4.1 days for a total of 202 patients. Of these, some two-thirds required tracheal intubation or tracheostomy and one-quarter mechanical assistance to ventilation.

It is our experience that "relaxant problems" commonly arise from unrecognized disturbances of metabolism or cardiovascular or respiratory function. The other groups were determined by assessment of the patient's history and clinical examination as well as radiographic and electrocardiographic findings. In this series there were instances where it was difficult to determine whether an upset in acid-base balance actually preceded rather than followed a period of cardiovascular depression or respiratory insufficiency.

It may be noted that difficulties involving the relaxant group of drugs alone were uncommon in both elective and emergency cases, and all such patients survived in this series, requiring merely prolonged assistance to ventilation. Only three cases of true suxamethonium apnoea were identified in this series. The high incidence of pre-existing lung disease, as diagnosed on clinical, biochemical, and radiological evidence, is not surprising in the City of Glasgow. The higher survival rate in the elective cases is taken as a reflection of the better pre-operative preparation of these patients and the ability to choose the optimal time during treatment for elective surgery.

Figs. 1 and 2 show the distribution of patients according to the site of operation, and indicate the comparative survival rates for the various procedures.

Two points arise with reference to the elective thoracic cases. Firstly, only a small percentage of the total number of admitted cases have had thoracic procedures, and these represent a minor fraction of the total performed in the hospital. Secondly, the higher survival rate compared with the elective upper abdominal procedures may reflect the fact that the thoracic cases are

usually more extensively assessed, and the operation if performed is done under optimal conditions.

Drug Poisonings

When respiratory failure complicates drug overdose, either accidental or self-administered, the patient is best treated in a respiratory intensive care unit working in close conjunction with a dialysis unit. Ideally, the two intensive care units should be adjacent, since more than one period of dialysis may be required, and this presents problems where the patient is still on intermittent positive-pressure ventilation. It is probably true to say that no patient need now die from the effects of barbiturate overdosage, since respiratory function can be supported almost indefinitely while forced diuresis or renal dialysis eliminates the drug. This view is supported by our experience of two remarkably high serum barbiturate levels successfully treated by this combined technique. One patient had an initial serum phenobarbitone level of 57 mg./100 ml. and the second had a serum butobarbitone level of 15 mg./100 ml. Both patients made a successful recovery (Kennedy *et al.*, 1967).

Nevertheless, only 37 patients out of 42 survived in this group, but those who died had already suffered prolonged severe hypoxia due to respiratory insufficiency before admission. Only two of these deaths were due to true barbiturate overdosage, the others being "mixed poisonings." Twenty-two of the patients were treated by forced diuresis and only three required artificial dialysis. No patient required a tracheostomy, endotracheal intubation with a cuffed tube being the method of choice at that time when an artificial airway was necessary (40 out of 42). The tracheal tube was not left in situ for longer than 72 hours in this group of patients, and their average stay in the unit was 3.1 days. Intermittent positive-pressure ventilation was necessary in 28 of the 42 patients.

Miscellaneous Cases of Respiratory Failure

Though this group of patients requiring respiratory intensive care is small in number, it comprises many of the most interesting and challenging types of respiratory disturbance. Table V details the individual conditions, and it can be seen that there is a variety of comparatively uncommon conditions represented here. The overall survival rate of 33.3% is low, but it must be remembered that only the most gravely ill patients with these conditions were admitted.

This miscellaneous group of patients averaged 9.8 days of treatment in the intensive care unit. A large proportion required tracheostomy (72.7%) and intermittent positive-

FIG. 1.—Analysis, according to site of operation, of 131 elective patients who developed postoperative respiratory insufficiency. The cross-hatched areas represent the percentage survival for each procedure. FIG. 2.—Analysis, according to the site of operation, of 71 emergency patients who developed postoperative respiratory insufficiency. The cross-hatched areas represent the percentage survival for each procedure.

pressure ventilation (63.6%). Tracheostomy was commoner than endotracheal intubation (20 out of 24 cases) mainly owing to the length of time required for treatment.

TABLE V.—Variety of Conditions in Which Acute Respiratory Insufficiency Required Energetic Treatment. All Required Active Measures to Support Respiration In Addition to Specific Therapy

Condition	No.

Obstructive Lung Disease

In the initial stages of the pilot respiratory intensive care unit those suffering from an acute exacerbation of chronic obstructive lung disease were admitted. Sixteen patients were treated during this period, 11 requiring intubation or tracheostomy and seven intermittent positive-pressure ventilation. These patients are now largely taken care of in a separate unit within the hospital, and this is highly desirable, since they tend to be an important source of infection and present a real hazard to the "clean" cases, particularly those in the traumatic group. If such patients are to be managed along with uninfected cases, there is no doubt that they should be isolated and if possible barrier nursed.

The standard treatment for this group of patients was controlled low oxygen therapy with the Edinburgh mask (Flenley *et al.*, 1963). Tracheal intubation was used rather than bronchoscopy to facilitate frequent and thorough aspiration of secretions. Tracheostomy was reserved as a last resort. Intensive physiotherapy is an essential part of treatment here, as indeed in all the patients treated in the intensive care unit, and this is combined with measures to stimulate coughing along with the appropriate antibiotic therapy.

Special Problems in Respiratory Intensive Care

Whatever the underlying cause leading to the episode of respiratory failure in an individual patient, certain common problems require consideration, and certain techniques have been evolved which are applicable to the treatment of all cases.

Cross-infection

Without doubt a major problem in a respiratory intensive care unit is the control of infection and the segregation of known infected cases. In the small four-bed unit the infection rate was high, and all tracheostomies became technically infected as judged by serial culture of tracheal swabs, though this did not necessarily result in intrapulmonary infection. In addition, a large number of these patients required indwelling urinary catheters, and, despite aseptic precautions, bladder infections were inevitable in most long-stay cases. The close juxtapositioning of the four beds, approximately 5 ft. (1.5 m.) apart side to side and 6 ft. (1.8 m.) apart end to end, defeated the most stringent aseptic precautions in the handling of tracheostomies. Again there was no provision for ventilation of the ward with filtered air, and the mechanical ventilators were not able to be adequately sterilized for the first two years. The main infecting organism was the resistant *Staphylococcus aureus*, but when this was eliminated by use of the newer potent antibiotics a secondary invasion with *Escherichia coli*, *Proteus mirabilis*, or *Pseudomonas pyocyanea* was common. The lack of cubicles prevented barrier nursing of known

infected cases, and resulted in a further increase in the infection rate. On those occasions when the infection rate reached epidemic proportions the unit was closed for thorough cleansing, including washing of walls from floor to ceiling.

Since early 1966 a new respiratory intensive care unit has been in use which represents a great advance, particularly from the point of view of control of infection. Fig. 3 shows the plan of this eight-bed unit, which is a conversion from a 26-bed Nightingale ward. Two large cubicles (dimensions 15 by 12 ft.; 4.6 by 3.7 m.) are available for the barrier nursing of selected cases, both patients known to be infected and those potentially infected—for example, those with superficial burns. In addition, the whole unit is ventilated with filtered warmed air by a plenum system with extractor fans at each bed station. Humidity of the air is also controlled. One cubicle can be separated from the plenum system and the atmosphere independently controlled by means of a standard office-type air-conditioning unit. The main advantage, however, in this new unit is that the beds are widely set apart in individual bays. Each bed station has its own trolley with all its own instruments—for example, Wright's respirometer and laryngoscope. No equipment or instrument is permitted to be transferred from one bed station to another. Entry to the unit is controlled by means of an interchange area, and all persons visiting the unit are required to wear gown, mask, and overboots. Such cases of known infection as have been admitted

FIG. 3.—Plan of respiratory intensive care unit. The interchange areas lie between the inner doors opposite the kitchen and nurses' staff-room. The laboratory, which is adjacent to but outside the unit, is not shown.

of necessity have been nursed in the cubicles without any evidence of cross-infection. The practice is for every patient to be swabbed (nasopharynx or trachea and skin) and a urine culture done at the time of admission. This latter test is repeated, if the patient is catheterized, at least twice weekly throughout the patient's stay. All staff have regular nasopharyngeal swabs taken.

A further advance in the control of infection has been in the sterilizing of the ventilators. These are now sterilized with ethylene oxide, after thorough cleansing, before being reused (Bishop *et al.*, 1962). In long-term cases these machines should be changed every three to four days. Currently an investigation is being carried out into the advantages of bacterial filters on the ventilators. A record is kept of the bacteriological history of each machine and its associated parts—for example, spirometer and humidifier—in order to facilitate tracing the source of any outbreak of pulmonary infection.

Oxygen Therapy

Controlled oxygen therapy is an important part of treatment in these patients. Control implies measurement, and this consists of regular oximetry to monitor the inspired oxygen concentration by means of the Beckman instrument. In addition, blood gases are measured at frequent intervals in all

acutely ill patients as a guide to the efficiency of treatment. This demands a "bedside" service, and the medical staff in the unit are all trained in the use of the appropriate apparatus to measure haemoglobin oxygen saturation, arterial oxygen tension, arterial carbon dioxide tension, acid-base state, and haemoglobin in the laboratory adjacent to the unit.

In addition to its function as originally described for administering controlled low-oxygen concentrations, the Edinburgh mask is also used, with the modification described by Campbell (1967), to administer inspired concentrations up to approximately 80%. The advantage of this system is that one basic disposable mask can be used for all types of oxygen therapy.

Metabolic Care and Nutrition

Intensive care demands a great deal of assistance from the biochemist. The measurement and restoration to normal of blood volume, hydration, and electrolyte levels are well understood.

One feature of patient care which often suffers neglect is the provision of an adequate nutritional regimen. This aspect of the care of the surgical patient is well described by Moore (1959). It applies to all patients, particularly those in an intensive care unit (Peaston, 1967).

The importance of adequate nutrition cannot be overstressed, since many of these patients suffer a severe catabolic response after injury or surgery, and this may be aggravated by concomitant infection when the calorific requirement may reach 4,000 calories a day. If muscle wasting is allowed to develop then "weaning" from the ventilator may be prolonged, despite a return to normal pulmonary function, since the patient is unable to perform the required work of respiration. The condition of such a patient can resemble that of a severe myasthenic.

Central Venous Pressure

The measurement of central venous pressure in the surgical patient (Sykes, 1963) is of value where there has been severe blood loss. A catheter can be introduced into the superior vena cava via the external jugular or an antecubital vein, but if this is impracticable a saphenous cut-down at the groin enables a wide-bore catheter to be introduced into the inferior vena cava. The presence of a caval cannula also enables parenteral feeding to be instituted at an early stage in treatment without the complications of peripheral venous thrombosis.

Monitoring of Vital Functions

It has been found invaluable to make use of a central monitoring system whereby E.C.G., heart rate, temperature, and respiratory rate can be observed continuously in every patient. The recording of these functions can be carried out even by a nursing-aide, thus enabling the more skilled nursing staff to carry out the heavy demands of patient care. Blood pressure is, in our experience, still best measured by the mercury sphygmomanometer at the bedside and only in special cases via an indwelling arterial cannula. Respiratory measurements carried out by the nurse include minute volume, airway pressure, and respiratory frequency when on intermittent positive-pressure ventilation, and respiratory frequency and minute volume when breathing spontaneously. Regular auscultation of both lung fields is also carried out by the nursing staff to detect any gross changes in air entry.

Intelligent use of modern technological aids can to some extent mitigate the shortage of skilled nursing personnel, though it must be remembered that monitoring devices are only an

extension of the nurse's own senses and not in any way a substitute for acute observation and constant attention at the bedside.

Organization and Staffing

The Glasgow Royal Infirmary respiratory intensive care unit not only serves the parent hospital but also provides a group service for the associated hospitals. Some 5% of cases, a figure which is increasing, come from other hospitals throughout the Western Region, and a small number are referred from hospitals outside this region. This intensive care unit is associated with other intensive care areas within the hospital—namely, the renal dialysis, cardiovascular-surgical, acute coronary, and medical respiratory units.

Medical Staff

The unit is administered by the department of anaesthetics. Three consultant anaesthetists share the senior duties on a sessional basis. Two anaesthetic registrars are in training at any one time, each for a period of two months, with no other duties. An anaesthetist is always on duty in the unit, where simple sleeping accommodation is provided. The medical staff are also responsible for the anaesthetic side of the hospital emergency resuscitation and cardiac arrest service, which is on a "crash call" basis. This ensures that experienced anaesthetic assistance is immediately available in appropriate cases. The importance of the integration of such an emergency service within the organization of the intensive care unit has been mentioned by Campbell (1965).

Ward rounds, at least four in a 24-hour period, are conducted by the consultant anaesthetist on duty. That is, apart from a primary concern with the patient's respiratory problem, the consultant is responsible for overall care. Administrative responsibility for the running of the unit cannot readily be separated from a clinical responsibility to the patients. Joint bedside examination and discussion of each case, if necessary several times throughout the 24 hours, is essential to full co-operation between the various specialists involved in the treatment of an individual patient. As a consequence, treatment is under continual review, continuity of care progressing from the intensive care unit to the general ward. This co-operative effort has been a most successful and rewarding feature of this work, and the advantages of the system have been stressed by Kennedy *et al.* (1963).

Nursing and Ancillary Staff

While the ideal number of trained nursing staff per patient has been variously estimated at from one to two per patient per shift (Nolan, 1965), the following staffing has been found adequate for most of the time in this respiratory unit: four sisters, two full-time and three part-time staff nurses, and two trained nurses assigned to the unit while on postgraduate intensive care training course; two student nurses; three full-time and two part-time State-enrolled nurses; two male orderly-technicians and one female orderly; one housekeeper; and one domestic.

An eight-hour shift system is not possible with these numbers and a "partial" shift system is operated. The working day is from 8 a.m. until 9 p.m., and night from 9 p.m. to 8 a.m., and this arrangement has not led to any lack of continuity in care. There is no doubt that, taking into consideration the demanding nature of the work, a two-day rest period a week is essential. Great use is made of ancillary nursing staff, who can all be employed in such a way that trained staff are relieved of the simpler but necessary non-nursing duties.

The contribution made by the physiotherapy staff deserves special mention. Their services have proved invaluable, and they are required throughout the 24 hours. Indeed, all

supporting services, laboratory and diagnostic, must be on a 24-hour seven-day week basis.

Despite the physically and mentally exhausting nature of the work morale is high. This is thought to be largely attributable to the fact that medical and nursing staff have been to some extent self-selective. In addition, there is the fullest discussion of all problems, theoretical and practical, between medical, nursing, and ancillary staff. This is carried out both at the bedside and in the form of lecture-tutorials. Finally, despite the high mortality rate, the successes have been such that no member of the staff requires any further demonstration of the value of the concept of intensive care for patients with acute respiratory difficulties.

Summary

It is suggested that an essential preliminary to the setting up of a new intensive care unit is the conducting of a preliminary survey of the hospital population to determine the likely number of patients requiring this degree of care. Such a prospective study, carried out in the Glasgow Royal Infirmary, to assess the total requirements for intensive care is described. The next step, which may be carried out simultaneously, is to set up a small "pilot" unit in which actual experience may be gained of the problems of organization and care of patients. The final phase, if indicated, is the establishing of a definitive unit for the intensive care of one or other group of patients—for example, respiratory problems, acute coronary cases, renal problems, etc.

The results of the intensive care of 488 patients with acute respiratory problems are presented. Certain aspects of organization and patient care involved in the treatment of these cases are discussed.

We should like to pay tribute to our colleagues of the medical and nursing staff of the Glasgow Royal Infirmary, whose co-operation, interest, and hard work have made the success of the respiratory intensive care unit possible. In particular we are deeply indebted to the staff of the Department of Physiotherapy for their invaluable contribution to patient care. We are grateful to the members of the committee who carried out the original prospective study on intensive care needs in the hospital, and the Board of Management of Glasgow Royal Infirmary for permission to publish the results given in Tables I and II.

Visuo-motor Disability in Schoolchildren

MAY WOOLF BRENNER,* PH.D.; SELMA GILLMAN,* PH.D.; O. L. ZANGWILL,* M.A.
 MARGARET FARRELL,† M.A.

Brit. med. J., 1967, **4**, 259–262

In a recent study the visuo-motor abilities of 810 schoolchildren (427 boys and 383 girls) aged 8–9 years were sampled by means of a new group test-battery. This comprised 11 tests designed to explore various aspects of visuo-motor capacity and to provide norms for the assessment of disability. The tests used could be classified under three general headings: (1) dexterity—for example, use of scissors and simple pencil control within guiding lines; (2) perceptual analysis—for example, the capacity to discriminate overlapping designs or to isolate figures "embedded" in more complex designs; and (3) constructional skill, as evidenced in block design, drawing, and other simple constructional tasks. Full details of the tasks and the principal findings are available elsewhere (Brenner and Gillman, 1966). In addition, verbal intelligence was measured with the standard National Foundation for Educational Research Verbal Test I. All testing was carried out by two of us (M. W. B. and S. G.).

A high correlation was found between scores on the visuo-motor test-battery and verbal I.Q. However, the inquiry brought to light 54 children (6.7%) with I.Q. above 90 whose scores on the visuo-motor test-battery deviated more than 1 S.D. from the means established for their I.Q. groups. The performance of these 54 children, who were equally divided between boys and girls, was so poor as to suggest a specific developmental disability. Despite the fact that verbal intelli-

gence was in no case below 90 (and not infrequently above 110), school performance was in general found to be poor, especially in regard to spelling, writing, and arithmetic—though reading was as a rule adequate. The characteristic most frequently remarked on in these children was *clumsiness* in gait, in movement, or in fine motor control. Untidy, careless, and slovenly school work was constantly reported.

In the 31 most seriously affected children the visuo-motor test scores deviated 2 S.D. or more from the mean. Fourteen children in this group who were still resident in the area and who remained available for continued follow-up study over a three-year period form the subject of the present report. Each of these children was matched for age, sex, handedness, verbal I.Q., and home and school background with a child drawn from the same sample who had shown no appreciable discrepancy between verbal I.Q. and the score on the visuo-motor test-battery. The children in both groups, which are termed the experimental and control groups, were retested one year after the initial examination, and their progress at school was followed for two further years. Information regarding previous history was obtained from parents, supplemented in some cases by reports from general practitioners. In interviews with parents and teachers, semi-standard forms of questionnaire were used, and no information was given on whether a particular child had been assigned to the experimental or the control group. All test data were scored by at least two of us independently.

* Psychological Laboratory, University of Cambridge.

† Child Psychiatric Clinic, Cambridge.

Intelligence Test Scores

The children in both groups were tested on the Wechsler Intelligence Scale for Children one year after completion of initial survey. In the experimental group the mean verbal I.Q. was 108.5 and the mean performance I.Q. 94.1. In the control group the mean verbal I.Q. was 110.1 and the mean performance I.Q. 115.6. Thus the discrepancy between verbal and performance I.Q. was 14.4 (V 7 P) in the experimental group and 5.5 (P 7 V) in the control group. This difference is significant at the 1% level (*t* test for small samples).

The marked inferiority of children in the experimental group on non-verbal tasks was shown also on a number of other standard tests which call for the exercise of spatial judgement and manipulative skill. These comprised the draw-a-man test (Goodenough, 1926); the Bender-Gestalt test (Bender, 1938),

both the Pascal and Suttell (1951) and the Koppitz (1964) scoring methods being used; the Stanford-Binet "plan-of-search" subtest (Terman and Merrill, 1937, Form L); a peg-board design test adapted from the Goldenberg Marble Board (Strauss and Kephart, 1955) and including an additional immediate memory test; and a right-left discrimination test (Benton, 1959). The results are shown in Table I. It will be seen that, with the sole exception of the right-left discrimination test, the differences in mean scores between the two groups (Goodenough, 1926; the Bender-Gestalt test (Bender, 1938), are all significant at the 1% level. In the case of the Bender-Koppitz, the scoring system measures number of errors; hence the lower the score the better the performance.

Birth and Medical Histories

The main findings relevant to birth history, previous illnesses, and present condition of the children in the two groups are presented in Table II. It would appear from this information that the children in the experimental group include a considerable number with indications of exposure to a variety of perinatal hazards. There are also definite indications of hyperkinesia, clumsiness, speech defects, or poor motor co-ordination in a high proportion of these children. In the control group, on the other hand, indications of prenatal or perinatal hazard, clumsiness, hyperkinesia, or poor co-ordination are virtually absent.

TABLE I.—Mean Scores and Standard Deviations on Seven Visuo-spatial Tests

Test	Maximum Score	Experimental Group		Control Group		Difference
		Mean	S.D.	Mean	S.D.	
Draw-a-man	25	7.39	3.30	16.25	3.08	8.86*
Bender-Gestalt	30	14.07	3.10	27.79	1.57	13.72*

In their developmental history there was a definite suggestion that the children in the experimental group had been slower in attaining their "milestones" than the control children. Eleven mothers of children in the former group volunteered the information that they thought their children were clumsy or had particularly poor fine motor co-ordination. (Typical comments were: "He'd fall over a match-stick"; "She's absolutely useless with her hands"; "It took him twice as long as it should to learn to ride a bicycle.") Several of these mothers also confessed that their children had been very slow to learn to dress themselves, their greatest difficulty having been in learning to tie shoe-laces or fasten buttons.

Educational Status

Information from school records and interviews with teachers disclosed that only two of the children in the experimental group were thought to have made satisfactory progress at school. In the control group, on the other hand, only two children were thought to have had any difficulties at school.

The school subjects which presented the greatest obstacles to the children with visuo-motor handicap were spelling and arithmetic. In the case of arithmetic, difficulty lay less in connexion with basic principles than with the layout of written work. Handwriting was almost always poor, and two children were backward in reading.

Despite the fact that the two groups were so closely matched for verbal intelligence, only one child with visuo-motor handicap passed the eleven-plus examination, as compared with five children in the control group. Among the failures in the experimental group were a boy with a verbal I.Q. of 137; another, with an I.Q. of 128, refused even to sit the examination because of his anxiety about arithmetic.

As might be expected, the children in the two groups differed greatly with regard to interests and hobbies. In the control group 11 children enjoyed model-making, carpentry, jigsaws, or, in the case of girls, knitting or sewing; in the experimental group, on the other hand, not a single child enjoyed any of these activities. Only one child in the experimental group, as compared with eight children in the control group, was reported to be at all proficient at games.

Ratings by teachers of a number of personality traits revealed marked differences between the two groups. Whereas there was little difference in the case of traits such as concentration or persistence, most children in the experimental group were regarded as clumsy, awkward, untidy, and inept on the sports field. Two were rated as overactive. Most of these children tended to be described by teachers as particularly irritating, difficult, lacking in self-confidence, and unpopular with their peers.

Emotional Adjustment

According to their parents, six children in the experimental group and 12 in the control group were normal or well-adjusted. Seven in the experimental group and two in the control group were said to have shown some behaviour disorder. This was described as severe in three cases, two of which were in the experimental group. At the same time it is noteworthy that only two children, one in each group, had on any occasion been referred to a child-guidance clinic.

Discussion

It is significant that the children with visuo-motor handicap described in this paper were identified not by referral from clinics or hospitals but by screening a supposedly normal school population. Indeed, only one child had ever been referred to a child psychiatric clinic, and then on account of emotional rather than perceptual-motor disability or difficulty in learning.

Yet most of these children had for years been regarded by their parents as abnormally awkward or clumsy, and by their teachers as untidy, difficult, and irritating. In spite of mounting problems at school, none had been referred to the educational psychologist or the child-guidance services.

Somewhat similar cases have been described by Walton, Ellis, and Court (1962) and Gubbay, Ellis, Walton, and Court (1965). Our findings bear out the contention of Gubbay *et al.* that developmental agnosic-apraxic syndromes are a great deal more common than is generally supposed. We can also confirm their allegation that when these disorders are present without obvious neurological signs the children affected seldom receive the understanding and sympathy which might be thought their due. As these authors point out, such children are often accused of laziness or misbehaviour, or suspected of being mentally dull. "The natural outcome is a feeling of frustration, often leading in turn to a behaviour disorder which aggravates the child's problems of learning and performance" (Gubbay *et al.*, 1965).

Though the similarity between developmental and acquired agnosic-apraxic defects should not be overstressed, the resemblance between the visuo-motor difficulties displayed by these children and those of neurological patients with posterior cerebral hemisphere lesions (Critchley, 1953) is too striking to be ignored. Though the element of unilateral neglect is lacking, the failures in spatial judgement and the difficulties in carrying out simple assembly and constructional tasks are almost identical with those displayed by patients exhibiting visuo-spatial agnosia or constructional apraxia. It is also noteworthy that constructional apraxia in adults is often associated with defects in spelling and calculation, which were also noted in our children with visuo-motor handicap. Similar findings in some children with developmental dyslexic syndromes have been described by Kinsbourne and Warrington (1963).

The aetiology of visuo-motor and kindred defects in otherwise healthy children has been discussed by Gubbay *et al.* (1965), who call attention to the not infrequent incidence of minimal signs of pyramidal or cerebellar dysfunction, to mild grades of E.E.G. abnormality (as a rule diffuse though occasionally focal), and to a high incidence of perinatal abnormality. These findings led them to the conclusion that underlying brain damage is responsible in a majority of cases. Though no formal neurological examination could be undertaken in the present inquiry, there was evidence of clumsiness or poor motor co-ordination in 11 children in our group with visuo-motor handicap and of hyperkinesia in two. There was also evidence of perinatal abnormality in at least six cases. It is probable, therefore, that a minimal grade of organic cerebral dysfunction underlies visuo-motor impairment.

It may be urged that a need exists for the early detection and proper management of children who present agnosic-apraxic disabilities of the type described in this paper, irrespective of whether or not they are associated with obvious neurological signs or with educationally more prominent defects such as developmental dyslexia. From an educational point of view, visuo-motor handicap has important implications for academic progress, secondary-school selection, and choice of career; and its relatively high incidence in a "normal" school population should be appreciated by teachers and educational authorities generally. From a psychiatric point of view, early detection and recognition of agnosic-apraxic disorder would do much to allay parental anxiety and to reduce the incidence of consequent psychiatric disturbances. It should be added that research into the degree to which the disability may be overcome, or compensated, by appropriate remedial training is urgently needed.

Summary

A survey of visuo-motor ability in a sample of 810 healthy schoolchildren brought to light 54 cases (6.7%) in which

performance was so deficient as to suggest a specific developmental failure. Fourteen of these children were matched for age, sex, handedness, verbal I.Q., and home and school background with an equal number of children drawn from the same sample who had shown no evidence of selective visuo-motor impairment. Both groups were followed up for a three-year period.

The children with visuo-motor defect were found to be significantly inferior to the controls on a series of tests of spatial judgement and manual skill, to present a variety of educational problems, especially in regard to spelling and arithmetic, and to give evidence of a relatively high incidence of maladjustment. There was also evidence of a relatively high incidence of perinatal abnormality in this group, raising the possibility of minimal early brain damage.

This study supports the contention that agnosic-apraxic disabilities in otherwise normal children are by no means rare and warrant wider recognition.

This work is supported by a grant from the Spastics Society. We wish to express our thanks to the Cambridgeshire County

Education Department and to the many head teachers and others who helped us in the work, not least the children themselves and their parents. Mrs. P. Koskinen gave assistance in testing and Dr. J. L. Gedye helpful advice on the preparation of this paper.

Effect of Salicylates in Urticaria

MIRIAM MOORE-ROBINSON,* M.D., M.R.C.P.; ROBERT P. WARIN,* M.D., F.R.C.P.

Brit. med. J., 1967, 4, 262-264

The ingestion of aspirin often seems to be responsible for attacks of urticaria and it has been assumed that there is an immunological basis for this effect. However, in the past few years it has been realized that in some patients with chronic urticaria which is apparently unrelated to food or drug allergy an exacerbation may be caused by taking aspirin (Calnan, 1957; Warin, 1960). The purpose of this investigation was to determine the incidence of this phenomenon and whether there are any clinical differences between patients with chronic urticaria who react in this way to aspirin and those who do not. In addition, we wished to discover which part of the aspirin molecule was responsible and whether the effect extends to the physical urticarias and weals induced by intradermal injections of histamine.

Subjects and Methods Used

Patients included in the study were drawn from those routinely seen in the outpatient department at the Bristol General Hospital. Others were referred to us by colleagues and in answer to a circular sent to general practitioners in the area. For the purpose of this study we have defined chronic urticaria as urticaria without an obvious cause which had been present for at least six weeks. All the patients had dermal weals, most of them also had attacks of angioedema. A few who presented with angioedema had had at some time a phase of dermal wealing. A total of 228 patients have been studied. The proportion of males to females was 1:1.7, and ages ranged from 3 to 71 years.

As part of a detailed interview patients were questioned regarding the ingestion of aspirin or aspirin-containing compounds, and any association with an increase in weals. If there was any possibility of exacerbations from this cause an aspirin test was carried out. This was done on a patient-blind basis, and consisted of control inert tablets identical in size, colour, and taste to aspirin labelled "A" and aspirin

tablets labelled "B." The inert tablet was always taken first, as it was felt that if the patients were given the aspirin first and reacted badly to it they would be reluctant to take the second tablet and so invalidate the test. A and B tablets were taken on consecutive days, the dose varying according to the history. Thus if the history were suggestive of an aspirin reaction the initial dose was 300 mg., whereas if the history were less certain it was 600 mg. of aspirin. Any change in the skin and the timing of such a change was noted by the patient. In eight patients the provocation tests were repeated with increasing doses of aspirin. In 21 of the patients who reacted to the test doses these were repeated with sodium salicylate (18 patients) and phenyl salicylate (3 patients) in equivalent molecular doses.

In order to assess the effect on physical urticaria 10 patients with dermographism, five with cholinergic urticaria, and three with cold urticaria were studied. Measurements in all cases were carried out four hours after administration of an inert tablet and later aspirin (300 or 600 mg.). In the dermographic patients a standard method of measurement of the wealing tendency was evolved. A spring-loaded blunt-ended projection which could give known pressure effects of 60, 120, 180, and 240 g. was applied to the volar surface of the forearms in a 3-4 cm. line through a piece of thin metal, cut to admit the projecting point. The width of the weals was measured direct after seven minutes and a graded response to the different pressures obtained. Patients with cholinergic urticaria were exercised for 10 minutes and the amount of wealing was assessed clinically by the patient and the observer. In cold urticaria the size of the weal produced by contact with ice for 10 minutes was difficult to measure and was again assessed clinically. Four patients with urticaria pigmentosa were also studied and weals measured with the same method as used in the dermographic patients before and after aspirin.

In a group of 14 patients comprising four who had reacted to the aspirin test and 10 who had not, the effect of aspirin on induced histamine wealing was decided by measuring the weals produced by intradermal injections of

* The United Bristol Hospitals.

0.05 ml. of 0.0001%, 0.001%, and 0.01% histamine acid phosphate solution on two separate occasions—the first four hours after the control tablets and the second four hours after 600 mg. of aspirin. Weals were measured by first taking a tracing of the weal and then transferring this to millimetre graph paper. An accurate measurement of surface area could be calculated by counting the squares in the outline of the weal.

Results

Out of the 228 patients with chronic urticaria, from the history, there appeared to be a possibility of an exacerbation caused by taking an aspirin-containing compound in 112, and in these the provocative test was carried out. There was no response in any case to the inert tablet, but 50 patients reacted to aspirin. This was usually felt within four hours. Pruritus, often of the lips and eyes, was the first symptom, and was followed by the development of widespread weals, and in many cases swelling of the lips and eyelids. The attack settled in a time varying from a few hours up to four to five days, but a few patients noted that the worsening from one dose of aspirin lasted for several weeks. It was thus shown that aspirin had an exacerbating effect in at least 22% of all the patients with chronic urticaria.

Of the eight patients tested with increasing doses of aspirin, four failed to react at all to 300 mg. of aspirin and had successively worse reactions with 600 and 1,200 mg. In four others the reaction worsened so markedly between 300 and 600 mg. of aspirin that a third dose was not given.

Furthermore, this quantitative effect was supported by clinical observations in other patients who commonly reported that they had taken a single aspirin without effect, but on occasion had ingested a larger dose over a short period—for example, two tablets (600 mg.) four times a day for two days—with the result that their urticaria became worse.

Of the 21 aspirin reactors on whom provocative tests were performed with compounds chemically related to aspirin, 13 out of 18 suffered worsening of their urticaria after sodium salicylate and two out of three after phenyl salicylate.

In the 10 patients with dermatographism the measurement of the weal width was in no case greater after aspirin than after the inert tablets. The weal size in the four cases of cold urticaria did not appear to be larger after aspirin. The five patients with cholinergic urticaria also showed the same degree of wealing after exercise with both the aspirin and inert tablets. Thus no effect of aspirin on these physical urticarias was demonstrated. The four cases of urticaria pigmentosa showed no increase in the width of weal after aspirin as compared with the inert tablets, and none had any general reaction to it.

The 14 patients in whom the effect of aspirin on induced histamine wealing was assessed can be divided into two groups; the first comprising 10 who had not reacted to the test dose of aspirin and in whom the histamine weal size was not different before and after aspirin, and the second com-

prising four who had reacted to aspirin, in whom the histamine weals were significantly larger after aspirin (Tables I and II). Table I shows the weal size in both groups four hours after ingestion of inert tablets. There is no statistical difference between the two sets of figures. Table II shows the same measurement four hours after taking 600 mg. of aspirin. The weal surface area in the four patients who had reacted to aspirin is obviously much greater—($P=0.001$). The reaction to 0.05 ml. of 0.0001% histamine acid phosphate solution was such in all four patients that intradermal tests with higher concentrations of histamine were not attempted.

TABLE II.—Weal Surface Area Measured Four Hours After Ingestion of 600 mg. of Aspirin

0.05 ml. Histamine Acid Phosphate Solution Intradermally	Non-reactors (10 Patients)		Reactors (4 Patients)	
	Actual Areas (sq. mm.)	Mean (S.E.)	Actual Areas (sq. mm.)	Mean (S.E.)
0.0001%	67, 69, 70, 73, 75, 76, 77, 79, 80	74 (± 1.4)	275, 281, 288, 296	285 (± 4.5)
0.001%	173, 177, 181, 184, 186, 186, 187, 189, 193, 194	185 (± 2.1)		
0.01%	285, 286, 288, 292, 295, 301, 305, 306, 306, 306	297 (± 2.8)		

Further clinical observations of the series of patients revealed points of interest. Firstly, there would appear to be no clinical difference or variation in the pattern of urticaria between those patients who react to aspirin and those who do not. There was evidence that the effect of aspirin becomes apparent in a susceptible individual only when several factors are acting at the same time. Patients often mentioned that a head cold, sore throat, gastrointestinal upset, period of anxiety, plus taking a large dose of aspirin exacerbated their urticaria.

The urticarial tendency in patients with chronic urticaria fluctuates in degree, and the severity of an aspirin-induced exacerbation is greater when the wealing tendency is pronounced. Thus patients who have shown a reaction with 300 mg. of aspirin, at a later stage when the wealing tendency was less have had little or no reaction with 600 mg., and in some patients tested when the urticaria had cleared an aspirin effect has been obtained only when doses up to 2,400 mg. of aspirin have been given.

Another interesting clinical association was that of the 50 patients who developed an exacerbation after aspirin four also had exacerbations after both penicillin and antitetanus serum on different occasions.

The series include four families in which successive generations have suffered from chronic urticaria and exacerbations due to aspirin. In one, the mother, who had suffered from chronic urticaria for 17 years, was shown to react to aspirin and sodium salicylate. One of her sons has had urticaria for nine years and is also an aspirin reactor. In one of our youngest patients, aged 4, who has had urticaria since the age of 18 months, wealing is increased after aspirin and also penicillin; her mother and one maternal aunt suffer from chronic urticaria which is severely increased after taking aspirin.

Discussion

It is difficult to understand the mechanism of this weal-exacerbating effect of aspirin in 22% of patients with chronic urticaria. A nonspecific histamine-liberating effect has been suggested, and Hamrin (1957) described a case of a patient with urticaria pigmentosa who developed flushing, vomiting, and collapse after aspirin, and it was considered that this result was due to histamine release. However, we have been unable to repeat these observations in the four patients with urticaria

TABLE I.—Weal Surface Area Measured Four Hours After Ingestion of Inert Tablets

	Actual Areas (sq. mm.)	Mean (S.E.)	Actual Areas (sq. mm.)	Mean (S.E.)
0.0001%	59, 62, 65, 68, 70, 70, 71, 71, 71, 71	68 (± 1.5)	68, 69, 72, 75	71 (± 1.6)
0.001%	185, 188, 189, 192, 195, 198, 200, 200, 201, 202	195 (± 1.9)	195, 199, 201, 209	201 (± 2.9)
0.01%	274, 276, 278, 280, 281, 283, 285, 288, 292, 293	284 (± 2.0)	284, 289, 296, 307	294 (± 5.0)

pigmentosa, and, moreover, on pharmacological grounds it would be unlikely for aspirin, an acid substance, to have such an action, as most recognized histamine liberators are bases.

Another possibility would be that aspirin was acting as a hapten, forming an antigen when combined with serum proteins. We have no clear evidence against this, but we would have to assume that at least one in five patients who suffered from chronic urticaria would also have such an allergy to aspirin.

That aspirin in some way renders the skin in these patients more sensitive to histamine is suggested by the present report that intradermal histamine weals were larger after aspirin in these patients. In this connexion it is interesting that Juhlin and Rune (1962) have reported that the threshold to 48/80, a known histamine liberator, is lowered in acute urticaria.

It has been stated in the past that aspirin sensitivity is specific to acetylsalicylic acid and does not extend to related compounds. In the present investigations similar reactions were obtained in most patients from sodium salicylate and phenyl salicylate, and it would seem likely that it is the salicylic acid radical which is responsible for aspirin reactivity.

Whatever the underlying cause, it is now established that a point of great practical importance in the management of patients with urticaria is to avoid any administration of salicylates.

The investigation of a patient with chronic urticaria, aspirin reactivity, and jaundice revealed abnormal liver histology described as atypical portal cirrhosis. This finding prompted the investigation of all patients who reacted to aspirin. To date, two other similar cases have been found. It is intended to report later the details of these three cases with the triad of chronic urticaria, aspirin reactivity, and liver disease.

Summary

Aspirin-containing drugs will cause exacerbation in some patients with chronic urticaria. In 112 out of 228 patients with chronic urticaria such a reaction could not be excluded

from the history, and provocative test doses of aspirin were given; 50 patients (22%) developed a well-marked increase in the urticaria. No clinical differences could be observed between the patients who reacted in this way and those who did not.

This action of aspirin is probably due to the salicylic acid radical, as most patients tested have had similar reactions with doses of sodium salicylate and phenyl salicylate.

It has been shown in eight patients that the increase in wealing is proportional to the dose of aspirin administered. In four patients who did not react at all to 300 mg. of aspirin there were successively more severe reactions to 600 and 1,200 mg. In four others the reaction increased so much between 300 and 600 mg. that a larger dose was not given. The quantitative effect is further supported by the clinical observation that some patients have developed exacerbations when large doses of aspirin have been taken and have shown no reaction to isolated small doses.

With appropriate measurements, before and after aspirin, it has been shown that there was no effect on the physical urticarias, including 10 patients with dermatographism, five with exertion urticaria (cholinergic), and three with cold urticaria. Similarly, no effect was demonstrated in the wealing in four patients with urticaria pigmentosa.

It has been demonstrated that induced intradermal histamine weals measured four hours after 600 mg. of aspirin were larger in a group of patients who had reacted to aspirin than in a control group. It is suggested that the mode of action of aspirin in chronic urticaria is by enhancing the effect of histamine in the skin.

This work was carried out with the help of an M.R.C. grant, and we should like to express our thanks for this. We also wish to thank Dr. C. D. Evans, Dr. R. R. M. Harman, and other colleagues who have so kindly referred cases to us. We are grateful to Mr. F. Wellington, Chief Pharmacist, Bristol General Hospital, who gave us invaluable help.

Clinical Measurement of the Anti-inflammatory Effects of Salicylates in Rheumatoid Arthritis

P. L. BOARDMAN,* M.D., M.R.C.P.; F. DUDLEY HART,* M.D., F.R.C.P.

Brit. med. J., 1967, 4, 264-268

Salicylates in relatively low dosage modify certain components of the inflammatory reaction in animal experiments (Adams and Cobb, 1963). Theoretically they may be used in rheumatoid arthritis to promote the relief of pain or for their anti-inflammatory effect. It is important to determine whether there is a different dose-response relationship for each of these characteristics.

The cardinal signs of inflammation—pain, heat, redness, and swelling—are the indices available for the direct clinical assessment of inflammatory activity in rheumatoid arthritis. Pain is subjective and difficult to quantitate. Joint heat was studied by Smyth and Clark (1957) and by Vaughn, Howell, and Kiem (1959); it was found to be of little value. The latter authors also found redness an unsatisfactory index for assessment. Hart and Clark (1951) introduced the method of standard

jewellers' rings for the measurement of joint size, by which accurate serial recordings could be made.

Fremont-Smith and Bayles (1965) investigated the effect of high dosage of salicylate in 11 patients in hospital with rheumatoid arthritis. Aspirin was given orally in increasing quantity over a five-day period until the largest tolerated dose was reached—on average, 5.2 g./24 hours. In most cases dosage increase was stopped because of tinnitus or deafness. Potent analgesics without anti-inflammatory action were then abruptly substituted. An increase in joint size, measured by standard jewellers' rings, and deterioration of grip strength, symptoms, and other indices followed rapidly the withdrawal of aspirin. They concluded that all patients with active rheumatoid arthritis, whether it was mild or severe, should receive salicylates regularly in the largest tolerated dosage in the absence of obvious contraindications. Because of side-effects "blind" techniques and quantitation of the changes were not attempted.

* Westminster, Hospital, London S.W.1.

A further point requiring critical consideration is whether the rebound deterioration following cessation of treatment is the direct consequence of the withdrawal of an anti-inflammatory agent or whether more complex mechanisms are of significance (Bywaters, 1963).

The aim of this study was to establish a quantitative method for measuring joint size by a technique based on the use of standard jewellers' rings under double-blind controlled conditions, and to differentiate reduction of swelling, an index of anti-inflammatory activity, from pain relief or analgesic effect with various doses of salicylates.

The results of the following four trials are reported: (1) comparison of prednisone with placebo to determine the effect of a known anti-inflammatory agent; (2) comparison of paracetamol with placebo to determine the effect of a known analgesic agent; (3) comparison of high dosage of salicylate with low dosage; and (4) comparison of low dosage of salicylate with placebo.

Material and Methods

Each trial was in the form of a double-blind cross-over comparison. The results were expressed sequentially, preference being based on alteration of joint size during the two periods.

All patients had classical or definite rheumatoid arthritis (American Rheumatism Association, 1959) of at least one year's duration. They were selected from consecutive attenders at the rheumatism clinic provided that they had synovitis of the small joints of the hands and that there was no history of intolerance to the relevant drugs. Only those patients were included in whom it was possible to stop all treatment for 14 days before the trial.

In trial 1 prednisone 7.5 mg. daily was compared with placebo, both being administered as a single evening dose. In trial 2 paracetamol 6 g. daily was compared with placebo; each was administered as three tablets four times daily. In trial 3 high dosage of salicylate was given at 5.3 g. (80 gr.) daily in four equal doses and low dosage at 2.6 g. (40 gr.) daily. In trial 4 low dosage of salicylate, 2.6 g. daily, was compared with placebo.

Each drug was given for seven consecutive days, each trial lasting 14 days. All tablets were taken after food. Salicylate was given in its glycinated form as a single tablet containing 660 mg. (10 gr.). After each treatment period the bottles were collected and the number of tablets remaining was checked.

Patients were interviewed a minimum of four times at weekly intervals in each trial. At the first visit joint size and grip strength were measured. These indices were measured again at the second visit. If the difference in joint size was less than 4 mm. and the overall change of grip strength less than 50 mm. Hg they were regarded as having a stable baseline and the trial was started. In those with greater changes further baseline assessment was made until the indices became stable. At the third visit—the end of the first seven-day trial period—the indices were measured and side-effects recorded, direct questions being avoided. The same programme was followed at the fourth visit, which marked the end of the trial, and the individual preference for either of the treatment periods was noted.

Joint size was measured as the circumference of the proximal interphalangeal joints of the four fingers of each hand, and the distal interphalangeal joint of each thumb—that is, the sum of the circumference measurements of the 10 digits. It was measured by a gauge (Fig. 1), the actual readings being recorded to the nearest millimetre. This gauge was used instead of standard rings, as it is quicker, the result is less likely to be influenced by the frictional state of the skin, and the tension at which it is applied is probably more consistent, particularly

over a tender joint. It is also preferred by the patient. The possibility of error developing at the extreme ranges of the scale because of variation in tension of the plastic spring was considered, but comparison against the rigid standard rings excluded significant inaccuracy. In Fig. 2 the results of 100 pairs of measurements of joint size with the two instruments are plotted. There is good correlation throughout the whole range.

Grip strength was measured for each hand with the cuff inflated to 30 mm. Hg, the result of a single sustained squeeze being recorded.

Joint size was measured before grip strength, or preference was assessed to avoid bias from knowledge of the other indices. The measurements were recorded without knowledge of those obtained at the previous visit.

One observer (P. L. B.) carried out all assessments. Variation between observers may be responsible for differences greater than significant changes in joint size. Table I gives the results obtained by observers in practice and those without previous experience of the method. Each of three observers with previous practice measured the joint size of 10 patients with rheumatoid

FIG. 1.—Photograph of gauge for measuring joint size in millimetres; standard jeweller's rings are also shown.

FIG. 2.—Comparison of 100 measurements of joint size made on the gauge with those obtained with standard rings. Coefficient correlation 0.948.

arthritis twice at an interval of an hour. The average difference between the two readings was 3.0 mm. For three observers without previous experience of the method, under similar conditions, the mean difference was 4.5 mm.

All patients were seen at the same time of day. In a group of eight patients in hospital with active rheumatoid arthritis there was an apparent decrease of joint size throughout the day (Fig. 3). The grip strength was greater in the evening than in the morning, the usual diurnal pattern (Wright, 1959), but the difference was not statistically significant.

TABLE I.—Observer Variation. Comparison of Results Obtained by Three Observers with Previous Experience of the Method with Similar Readings made by Three Without Prior Practice

FIG. 3.—Diurnal variation of joint size and grip strength in eight patients with rheumatoid arthritis. Joint size is measured in millimetres (+ indicates improvement). Grip strength is measured in mm. mercury, the sum for each time being plotted.

To express the results sequentially it is necessary to define a significant difference of joint size. In 50 outpatients with rheumatoid arthritis joint size was measured twice at an interval of seven days (Table II). The readings at the beginning and end of the week differed by 3 mm. or less in 42 (84%) of the patients. The mean difference was 2.12 mm. (S.D. 1.4). In eight patients (16%) the difference was 4 mm. or greater. A difference of 4 mm. was therefore arbitrarily assumed to be significant over a seven-day period.

Results

Trial 1: Prednisone v. Placebo.—A significant decrease of joint size on prednisone compared with placebo was reached after plotting 11 results (Fig. 4). As there was a difference of less than 4 mm. of joint size in two patients, the total number involved in the trial was 13. There was a significant increase in grip strength on prednisone compared with placebo in those patients in whom there was reduction of swelling. The mean grip strength on prednisone was 379 mm. Hg and on placebo 292 mm. Hg ($t=2.3$; $n=20$; $0.05>P>0.02$). The preference was for prednisone in 8 of the 11 patients, 1 preferred placebo, and 2 found no difference.

Trial 2: Paracetamol v. Placebo.—There was no significant difference of joint size in patients on paracetamol compared with placebo (Fig. 5). Of the 14 fulfilling the criteria for inclusion in the sequential analysis seven had less swelling on paracetamol and seven on placebo. Four patients were excluded from this trial because they had inadequate alteration of joint size. The 14 patients included in the trial had a mean improvement of grip strength from 303 mm. Hg on placebo to 326 mm. Hg on paracetamol. This difference is not significant ($t=0.57$; $n=26$; $P>0.05$). The preference was for paracetamol in six and for placebo in three patients, five finding them to be equally effective.

Trial 3: High Dosage of Salicylate v. Low Dosage.—There was a significant decrease of joint size on high dosage of salicylate compared with low dosage after 14 results were plotted (Fig. 6). In four patients joint size did not change sufficiently for inclusion in the analysis. The mean grip strength was 322 mm. Hg on high dosage compared with 309 mm. Hg on low dosage. This difference is not significant ($t=0.3$; $n=26$; $P>0.05$). The high-dosage regimen was preferred by 11 patients and the low dosage by one, two noting no difference.

Trial 4: Low Dosage of Salicylate v. Placebo.—There was no significant difference in joint size on low dosage compared with placebo (Fig. 7) after 15 results were plotted. In nine patients joint size did not change significantly on either preparation: these were discarded from the analysis. The mean grip strength on low dosage of salicylate was 312 mm. Hg compared with 348 mm. Hg on placebo. In five patients the preference was for low dosage and in three for placebo, seven finding no difference.

Side-effects

In trial 1 two out of 13 patients had subjective reactions on prednisone.

In trial 2 side-effects occurred in 10 out of 18 on paracetamol—generally dyspepsia and drowsiness—compared with three on placebo, all of which were dyspepsia.

High dosage of salicylate (trial 3) was associated with side-effects in six out of 18 patients, the complaint being tinnitus in four and nausea in two. On low dosage giddiness and abdominal distension were each noted once.

In trial 4 four out of 15 had complaints on low dosage of salicylate. These were frequency of micturition (1), giddiness (1), and dyspepsia (2). Placebo was associated with side-effects in three patients, two complaining of depression and one of a hot feeling.

Discussion

Trial 1 illustrates the effect of a known anti-inflammatory agent. Significant reduction of joint swelling is associated with improvement of grip strength and preference for prednisone.

Trial 2 defines the pattern that is obtained from a known analgesic agent without anti-inflammatory action: There is no difference of joint size on paracetamol compared with placebo. Both grip strength and preference suggest that there is some benefit from paracetamol compared with placebo, though neither alters to a statistically significant extent.

These findings suggest that under certain conditions alteration of joint size may be related specifically to reduction of inflammation. Grip strength and preference are less specific indices in that they may also improve after the administration of analgesic agents.

In trial 3 high dosage of salicylate is associated with reduction of joint size when compared with low dosage. The preference is strongly in favour of high dosage. The mean grip strength is better on high dosage, though the change does not reach significant levels.

There is no difference of joint size on low dosage of salicylate compared with placebo, a point shown in trial 4. There is no difference of preference: the grip strength is better on placebo but not to a significant extent.

A possible disadvantage of sequential analysis is the introduction of selection, because experiments in which there is no significant difference are discarded. In our study this is accepted deliberately to exclude the patient who lacks reversible soft-tissue inflammatory swelling. The alteration of joint size that follows the administration of an anti-inflammatory agent is relatively small. It is impossible to determine beforehand which patients possess only irreversible joint swelling. The results obtained from comparative studies of groups are diluted by the presence of patients without reversible inflammatory swelling. Although trends may be demonstrated, this factor may prevent the attainment of statistically significant differences.

It is probable that selection is not of importance in trials such as those reported in this study, in which each patient serves as his own control. The only trial in which a relatively large number were excluded from analysis was the comparison of low dosage of salicylate with placebo, trial 4. The mean age of the 15 patients included was 42 years: 12 were females and three males. The mean age of those excluded was 46 years: six were females and three males.

The trial consisted of two periods, each of seven days. This short duration was chosen to minimize variation due to the natural history of the disease. It was thought preferable to keep the administration of prednisone to a minimum. It was noted in patients studied in hospital that changes in joint size after the administration of rapidly acting anti-inflammatory agents are rapid, often occurring maximally within 48 hours (Hart and Boardman, 1963). In the presence of a limited amount of inflammatory swelling it is possible that any factor promoting improvement is associated with reduction of joint size, provided the period of administration is long enough. In these circumstances differences may be demonstrated more clearly by comparing the rate of change during a limited period.

The use of a cross-over trial may be criticized, because subjects starting on an active agent may have less chance of responding

in the second trial period. Rebound exacerbation after corticosteroid withdrawal may also affect the findings. The results obtained suggest that this is relatively unimportant under these defined conditions. It is unlikely that the order of administration affected the objective measurement of joint size in the three trials involving placebo. In the comparison of high and low dosage of salicylate analysis revealed no pattern of response that might depend on the order of the drugs. In the first week on high dosage improvement of joint size occurred in five out of seven, and in the second week in 7 out of 11. In the first week on low dosage 1 out of 11 improved, and in the second week 1 out of 7. The mean improvement in joint size on high dosage of salicylate in the first period was +5 mm.; in the second period it was +4 mm.

Clinically, joint size may consist of irreversible swelling and potentially reversible disease, the latter including inflammatory oedema, stasis oedema, and vascular dilatation. Irreversible swelling is excluded by the sequential method of analysis. Vascular dilatation is relatively unimportant, as the mean increase of joint size in a group of eight patients with rheumatoid arthritis and in three healthy control subjects after exercise and heat was about 1 mm. for the 10 joints of the hands. The changes in joint size were not the result of the elimination of stasis oedema after increased activity from satisfactory analgesia, because paracetamol alone was not associated with alteration of joint size. The apparent diurnal variation of joint size may be related to immobility during the night. In a further attempt to avoid this factor patients were assessed in the afternoon. The changes of joint size are therefore most likely to reflect alteration in inflammatory swelling.

Side-effects were no problem. It is of interest that drowsiness or dyspepsia occurred in over 50% of those receiving paracetamol. Tinnitus was the main complaint on high dosage of salicylate.

These findings confirm the importance of administering high dosage of salicylates in rheumatoid arthritis, irrespective of symptoms and their severity, if the aim of treatment is the promotion of nonspecific anti-inflammatory action. Relief of pain by low dosage of salicylate appears to be strictly limited and anti-inflammatory activity nonexistent under the conditions defined.

The measurement of joint swelling is accurate under controlled conditions. The response is so small that factors such as observer variation and differences in the time of the day may introduce error greater than the actual response.

In comparative drug trials the unrestricted use of salicylates, to be taken by the patient whenever necessary for supplementary analgesia, affects the results obtained, particularly at high dosage. If the number of tablets ingested by each group is different there may be selective alteration of the criteria of inflammatory activity. The number of tablets ingested in each period is therefore not a satisfactory index of progress. Low dosage of salicylate should be avoided, as it is probable that in combination it affects the response to other agents of indices such as joint size. Jick, Pinals, Ullian, Slone, and Muench (1965), using sequential analysis, showed that the addition of aspirin in small doses (1.5 g. daily) increased the therapeutic efficiency of dexamethasone 0.75 mg. daily to the level of 1.5 mg. daily.

It is suggested that for the assessment of anti-inflammatory effect of rapid onset in patients measurement of joint size under controlled conditions may be used, the results being interpreted by sequential analysis.

Conclusions

Joint size may be measured serially with reasonable accuracy under controlled conditions for the clinical assessment of inflammation in rheumatoid arthritis.

The patient's preference and grip strength indicate improvement on drugs which are anti-inflammatory or analgesic agents; under defined conditions joint size is an index of specific anti-inflammatory effect.

The reduction of joint size by prednisone, an anti-inflammatory agent, is contrasted with the absence of change in paracetamol.

High dosage of salicylate, unlike low dosage, is associated with reduction in joint size.

There is no detectable difference between low dosage of salicylate and placebo in their effect on joint size.

It is suggested that high dosage of salicylate, unlike low dosage, has a clinically measurable anti-inflammatory effect. Suppression of inflammation is desirable in rheumatoid arthritis high dosage of salicylate is indicated independently of symptoms.

Unlimited use of high dosage of salicylate in trials may affect the findings. Low dosage modifies the response if given in combination. Salicylate intake should be eliminated from comparative trials of anti-inflammatory agents.

It is suggested that the plan of this trial provides a simple method for the clinical assessment of the anti-inflammatory properties of a rapidly acting drug.

We wish to thank Dr. Peter Fowler for providing the millimetre gauge for the measurement of joint size; Dr. E. Lewis-Fanning for statistical advice; and Mr. J. A. Baker, chief pharmacist at the hospital, for organizing the provision of tablets suitable for the trials. Our thanks are also due to many members of the unit and to students for assisting in the assessment of error, in particular for the work illustrated in Fig. 2.

The above work formed the basis of a paper read to the Heberden Society in June 1967.

Glyceryl Trinitrate in Angina Pectoris: Tablet or Aerosol?

G. SANDLER,* M.D., M.R.C.P.; G. A. CLAYTON,† M.B., CH.B.

Brit. med. J., 1967, 4, 268–270

Though many drugs have been used in the symptomatic treatment of angina pectoris almost the only one which has been consistently shown to be of benefit in relieving the myocardial ischaemia is glyceryl trinitrate. In a previous study it was shown to be of considerable value when used prophylactically, but no better than a placebo when given after an attack of anginal pain had developed (Sandler *et al.*, 1963). It has been suggested that this lack of effect of glyceryl trinitrate in relieving established anginal pain might be due to the time it took to dissolve in the mouth (Evans, 1963), so that by then the angina had improved spontaneously. In relation to this possibility the development of an aerosol preparation of glyceryl trinitrate seemed of considerable interest, since such a preparation would be rapidly absorbed in the lungs with more rapid arrival in the myocardium. Preliminary observations (G. G. Gensini, unpublished; A. Black, unpublished) suggested that glyceryl trinitrate aerosol was of value in treating angina, and it was therefore decided to undertake an objective evaluation of the aerosol preparation (Cardamist) in treating angina pectoris and to compare it with the standard tablet trinitrate preparation.

Patients and Methods

Twenty-three patients with well-authenticated and typical attacks of angina pectoris were studied. These subjects, aged from 39 to 69 years, comprised 20 men and 3 women. In all of them the angina had settled down to a stable pattern, and the duration ranged from 3 to 72 months, with attacks occurring from 3 to 40 times weekly. The presumptive cause of the angina was coronary artery disease in all 23, but only four had evidence of previous myocardial infarction.

All the patients were admitted to hospital for a period of six days for the trial, and a daily exercise tolerance was carried out in each of them. The type of test has been described in detail in an earlier publication (Sandler, 1961), and is based on a modification of the Master two-step test, the patient exercising over two steps, each 9 in. (23 cm.) high, until he develops angina or completes 100 circuits over the steps; the test is stopped immediately if significant ischaemic change appears in the electrocardiogram during exercise. In addition to conventional electrocardiography, recording chest lead V5 before and after exercise, the patient is monitored continuously during exercise by means of a radiocardiograph. By this means ischaemic change can be detected immediately, even if unaccompanied by anginal pain, and the exercise terminated (Sandler, 1967). Depression of the ST segment of plane or sagging contour lasting at least 0.08 second, in either the radiocardiogram or the V5, was taken as evidence of myocardial ischaemia (Lloyd-Thomas, 1961; Master and Rosenfeld, 1961; Bellet *et al.*, 1962). Junctional depression, when it occurred, was accepted as significant of ischaemia only when the QX/QT ratio exceeded 50% (Master and Rosenfeld, 1961).

The preparations studied were glyceryl trinitrate aerosol delivering 0.13 mg. of the drug per inhalation—the dose investigated being 0.26 mg. (two inhalations)—an identical placebo aerosol, and standard tablets of 0.5 mg. of glyceryl trinitrate. Study of the aerosol preparations was made on a double-blind basis, and the distribution of active and placebo preparations in each pair of aerosols was randomized. It was not thought necessary to include a placebo tablet with the glyceryl trinitrate tablet, since a previous double-blind study had confirmed the effectiveness of the latter in this type of trial (Sandler *et al.*, 1963). Each of the three preparations—glyceryl trinitrate aerosol, placebo aerosol, and glyceryl trinitrate tablet—was assessed when given both before exercise was

*Consultant Physician, St. Helen Hospital, Barnsley.
†Medical Registrar, St. Helen Hospital, Barnsley.

undertaken and after, so that altogether six exercise-tolerance tests were carried out in each patient, each acting as his own control. Each exercise test was made at the same time in the morning, in the same environment, and with the same medical and technical staff present. To minimize the effects of progressive rest in hospital on the performance of the exercise-tolerance tests, the three preparations were varied in their order of administration in successive patients as they came under trial; this scheme is shown more clearly in Table I. All patients were fully ambulant between the exercise tests.

A.1 = First aerosol
A.2 = Second aerosol
Tab = Glyceryl trinitrate tablet. B/E = Before exercise. A/E = After exercise.

In addition to the inpatient assessment all patients were asked to use the aerosols as outpatients after discharge from hospital, again on a double-blind basis, and were subsequently questioned on several aspects of their use—which of the two aerosols was found more effective, whether the aerosol was better than the glyceryl trinitrate tablets previously used in relieving anginal pain, whether there was any difficulty in using the aerosol in public, and, finally, if any side-effects had been encountered with the aerosols.

Results

Table II shows the mean number of circuits undertaken by the patients with the three preparations. The control observations in this and subsequent tables are those recorded when the drugs were given after exercise had been completed, so that no medication had been taken before the exercise. In addition to calculation of the mean values for the whole group, the differences in individual patients resulting from each of the three preparations have been analysed statistically, so that variation between different subjects was eliminated and any changes produced by the drugs would have become more apparent. In Table II there were no significant differences, either in the mean number of circuits or in the mean change in the number of circuits, between any of the three preparations when given before exercise.

Table III shows the influence of the three preparations given before exercise on the number of patients developing angina, the time taken for the angina to develop, and the duration of

TABLE II.—Mean Number of Circuits and Mean Change with Administration of Active Aerosol, Placebo Aerosol, and Glyceryl Trinitrate Tablets Before Exercise (23 Patients)

	Glyceryl Trinitrate Tablets	Active Aerosol	Placebo Aerosol
Control No. of circuits	80.0	81.5	80.9
Mean No. of circuits with drug	80.9	83.5	83.0
Mean change in No. of circuits	+0.6	+2.0	+2.1

TABLE III.—Incidence, Exercise Time, and Duration of Angina (Mean Values)

	Glyceryl Trinitrate Tablets	Active Aerosol	Placebo Aerosol
No. of patients with angina	8	8	7
Exercise time before angina (sec.)	332.7	350.3	280.9
Duration of angine (sec.)	371.3	339.1	404.0
Change in exercise time	+68.2	+14.5	+64.9
Change in duration of angine	158.9	158.9	218.0

the angina (no control value was available for the duration of angina, since the control observations are those recorded when drugs are given after exercise). No significant differences were apparent between the three preparations in the number of patients developing angina, the time taken for angina to occur, or in the duration of the angina.

Table IV compares the degree of ST depression occurring during exercise in the radiocardiogram and after exercise in both radiocardiogram and V5; it shows the mean values for the different groups and the mean of the changes produced in individual patients by all three different preparations administered before exercise was undertaken. Considering first the changes in the radiocardiogram during exercise, the least ST depression occurred when a tablet of glyceryl trinitrate was given before exercise, and when compared with the mean ST depression after placebo administration before exercise the difference was seen to only just exceed the 5% probability level. Though the mean ST depression following glyceryl trinitrate aerosol before exercise was also less than that with the placebo, the difference was not significant ($0.15 < P < 0.2$). The mean change in ST depression during exercise did not differ significantly between the three preparations. When the changes in the radiocardiogram after exercise are considered there was significantly less depression in the ST segment with glyceryl trinitrate tablets than with the placebo ($P < 0.05$), and again there was no significant difference between the active and placebo aerosols. The changes in V5 after exercise did not show any significant differences between the three preparations.

TABLE IV.—Comparison of Degree of ST Depression in Radiocardiogram and V5

	Glyceryl Trinitrate Tabs		Active Aerosol		Placebo Aerosol	
	No. with Changes	Mean ST Depression (mm.)	No. with Changes	Mean ST Depression (mm.)	No. with Changes	Mean ST Depression (mm.)
Mean ST Depression

	22	0	23	+0.05	22	+0.07

D/E = During exercise.

The duration of ST depression in the radiocardiogram and V5 is shown in Table V. When the three drugs were given before exercise no significant differences in the duration of ST depression were apparent between the glyceryl trinitrate either in tablet or in aerosol form, and the placebo. Similarly when the three preparations were given at the end of the exercise neither of the two active preparations significantly influenced the duration of the ST depression compared with the placebo.

Outpatient assessment showed that 10 patients regarded the active aerosol as more effective in relieving anginal pain, 11

TABLE V.—Duration of ST Depression in Radiocardiogram and V5 With Drug Administration Before and After Exercise

chose the placebo aerosol, while two regarded active and placebo aerosols as equally effective. When asked to compare the aerosol preparation with glyceryl trinitrate tablets five patients thought the active aerosol more effective than the tablets, and seven thought the placebo aerosol the more effective. Only two patients thought that tablets were better than aerosol. The only side-effect encountered with the active aerosols was headache, which occurred in six patients. Only one patient, a woman, thought that use of an aerosol preparation in public was embarrassing.

Discussion

The effectiveness of glyceryl trinitrate in the management of angina pectoris depends primarily on its route of administration. The sublingual route has been found to be most useful clinically (Riseman *et al.*, 1958); for when the drug is swallowed, even in greatly increased doses, it is much less effective and the onset of activity is considerably delayed (Russek *et al.*, 1953; Russek, 1956). The introduction of aerosol administration of glyceryl trinitrate theoretically offers more rapid absorption through the alveolo-capillary membrane, and enables more rapid access to the myocardium and coronary vessels by eliminating the mouth-to-lung circulation time, usually 10 to 12 seconds. In addition, more consistent and concentrated absorption is possible, since sublingual administration may be modified by local oral factors. In a comparative trial of the aerosol and sublingual routes of glyceryl trinitrate administration in 31 anginal patients, A. Black and M. Black (unpublished observations) found that the aerosol gave more rapid relief of angina than the tablets in 27 patients, but assessment was made solely on subjective criteria.

In the present objective study the aerosol preparation given before exercise was no more effective than the placebo aerosol in influencing the amount of exercise possible, the incidence and duration of angina, or the degree and duration of the ischaemic ST depression induced by exercise. On the other hand, sublingual glyceryl trinitrate given before exercise did significantly improve the amount of ST depression occurring both during and after exercise. Though the doses of the aerosol and tablet preparations were not similar, the dose of 0.26 mg. of glyceryl trinitrate in the aerosol form was regarded as a potentially effective dose, since an earlier study had shown that a 0.25-mg. tablet of glyceryl trinitrate favourably influenced exercise-tolerance tests in anginal patients (Sandler *et al.*, 1963). The lack of effect of the aerosol preparation in this study is unlikely to have been associated with defects in absorption from the lungs, since care was taken to exclude any patient with clinical or radiological evidence of pulmonary disease, and the development of headache in six patients using the active aerosol indicates that adequate absorption has occurred, at least in these subjects.

The mode of action of glyceryl trinitrate in angina still remains controversial. Though coronary vasodilatation occurs in normal subjects, doubt has been expressed on whether it develops in atherosclerotic subjects (Gorlin *et al.*, 1959). However, more recent work with radioactive flow techniques and cineangiography has confirmed that coronary vasodilatation can occur in anginal patients (Johnson and Sevelius, 1960; Sones and Shirey, 1962). It is likely, however, that production of coronary vasodilatation by glyceryl trinitrate is beneficial only when the drug is used before exercise, since maximal coronary vasodilatation has probably already occurred when angina has developed owing to release of powerful local vasodilator meta-

bolites by the hypoxic myocardium (Wiggers, 1954; Friedberg, 1966). Gorlin *et al.* (1959) believe that the main benefit of glyceryl trinitrate in angina is due to peripheral pooling in the venocapillary system, leading to a diminished venous return and consequent reduction of cardiac work. The earliest concept of the mechanism of action of glyceryl trinitrate is reduction of cardiac work owing to systemic hypotension (Brunton, 1897), but assessment of blood-pressure changes after glyceryl trinitrate administration, both in the present study and in a previous one (Sandler *et al.*, 1963), has shown that this is an inconstant and very variable factor. It is likely that the beneficial effects of this drug are due to a combination of its two main actions—coronary vasodilatation and reduction of external cardiac work.

Summary

A controlled double-blind objective evaluation of the use of an aerosol preparation of glyceryl trinitrate was made in 23 patients with typical angina pectoris, and the results are compared with a standard 0.5-mg. tablet of glyceryl trinitrate administered sublingually. Assessment was made by exercise-tolerance tests with continuous radiocardiographic monitoring during and after exercise, as well as a conventional pre- and post-exercise electrocardiogram. The dose of aerosol studied was 0.26 mg. delivered in two inhalations, and both aerosol and tablet preparations were assessed before and after exercise.

The active aerosol was no more effective than the placebo aerosol in favourably influencing the amount of exercise performed, the incidence and duration of angina, or the degree and duration of the ischaemic change in the electrocardiogram; these results applied to administration both before and after exercise. On the other hand, glyceryl trinitrate tablets significantly improved ischaemic changes in the electrocardiogram when given before exercise, but not when given after it.

It is concluded that the aerosol preparation of glycerol trinitrate used in the present trial is ineffective, and prophylactic sublingual administration of glyceryl trinitrate tablets still remains the treatment of choice.

We are indebted to Miss A. Swingler and to Mr. B. Bamford for their technical assistance in the electrocardiography. Dr. W. S. Ogden, of Nicholas Laboratories Ltd., kindly supplied the active and placebo aerosols.

Intravascular Coagulation in a Case of *Clostridium perfringens* Septicaemia: Treatment by Exchange Transfusion and Heparin

M. L. RUBENBERG,* M.D.; L. R. I. BAKER,† M.B., M.R.C.P.; J. A. McBRIDE,‡ M.B., M.R.C.P.

Brit. med. J., 1968, 4, 271-274

Clostridium perfringens (*Cl. welchii*) infection following an abortion has always been associated with a very high mortality, often as great as 80% (Toombs and Michaelson, 1928; Hill, 1936; Russell and Roach, 1939; Butler, 1945). Although the use of antibiotics in addition to antitoxin might have been expected to reduce the death rate, the fatality rate recorded by Mahn and Dantuono (1955) differed little from that of previous reports. Immediate hysterectomy (Decker and Hall, 1966), hyperbaric oxygen (Brummelkamp *et al.*, 1963; McAllister *et al.*, 1963; Brummelkamp, 1965), and exchange transfusion (Bessis, 1949; Funck-Brentano *et al.*, 1965) have also been used in treatment. The relative merits of these newer forms of treatment have not yet been clearly established.

The case we report presented with massive intravascular haemolysis and anuria, complicating *Cl. perfringens* septicaemia. It was thought likely that a state of intravascular coagulation was present and that this was being maintained by the release of thromboplastin from toxin-damaged red cells. Therefore, in addition to treatment with antibiotics and antitoxin, an immediate exchange transfusion was performed to remove as many of the damaged red cells as possible, and treatment with heparin was begun so as to stop the intravascular coagulation.

The effect of these measures on intravascular haemolysis, the level of coagulation factors, platelet survival, fibrinogen catabolism, and the level of fibrin degradation products in the serum are presented.

Methods

Routine haematological procedures were carried out as described by Dacie and Lewis (1963). Platelets were counted by the method of Brecher and Cronkite (1950). Platelet survival was measured by using ⁵¹Cr-labelled platelets prepared by the method of Morrison and Baldini (1967). Fibrinogen was estimated by the method of Ratnoff and Menzie (1951). Fibrinogen catabolism was measured, using fibrinogen prepared by the method of Regoeczi and Walton (1967) and iodinated by the ¹³¹I monochloride method of McFarlane (1963). The fractional catabolic rates of fibrinogen and the relative partition of the protein between the intravascular and the extravascular compartments were calculated by the method of Matthews (1957).

Fibrin split products were assayed in the serum by agar-gel immunodiffusion (Ouchterlony, 1958) and by the tanned-red-cell haemagglutination inhibition assay, using rabbit anti-human fibrinogen antiserum (Merskey *et al.*, 1966).

Fibrinolysis was assessed by measurement of plasminogen (Alkjaersig *et al.*, 1959), lysis of fibrin plates (Alkjaersig *et al.*, 1959), and euglobulin lysis time (Nilsson and Olow, 1962).

Case Report

A 32-year-old woman was admitted to hospital two days after an attempt to procure an abortion, after 12 weeks of amenorrhoea, by using a solution of Dettol (chloroxylenol sol. 5%) and water. On the day of admission to another hospital, 1 December 1966, she complained of pain in the lower abdomen and back, developed a foul vaginal discharge, and became oliguric. Her temperature was 100.4° F. (38° C.).

Examination of a peripheral blood film and a high vaginal swab stained by Gram's method revealed large Gram-positive encapsulated bacilli, and a heavy growth of *Cl. perfringens* was cultured from both blood and vaginal swab. She was treated immediately with cephaloridine 1 g. six-hourly, as there was a history of penicillin allergy, and gas-gangrene antitoxin 20,000 units intravenously. The next day, 2 December (Day 1), she was pale, jaundiced, and cyanosed, and because of complete anuria was transferred to Hammersmith Hospital.

Clinical Findings.—She was conscious, euphoric, and confused. She was febrile (101° F.; 38.3° C.) and hyperpnoeic (respiratory rate 40). The skin was a striking mahogany colour and the sclerae were yellow. Her nose and fingers were cold and blue, and diffuse magenta-coloured bruises were present on the left side of the neck and at venepuncture sites. The respiratory system was normal on percussion and on auscultation. The pulse was regular (120 per minute), and the jugular venous pressure was not raised. No cardiac murmurs were heard. Blood pressure was 105/55. There was marked lower abdominal tenderness with guarding. Bowel sounds were present. The vagina contained blood and necrotic material. The size of the uterus was felt to be consistent with a 12-week pregnancy. The optic fundi and cranial nerves were normal. Tendon reflexes were present and equal.

Laboratory Investigations.—Haemoglobin 7.2 g./100 ml.; P.C.V. 26%; M.C.H.C. 27%; reticulocytes 1.0%; white cell count 50,000/cu. mm. (segmented neutrophils 57%, non-segmented neutrophils 23%, metamyelocytes 9%, myelocytes 1%, lymphocytes 7%, eosinophils 1%, monocytes 2%); nucleated red blood cells 2 per 100 white cells; platelets 88,000/cu. mm. The peripheral blood film showed striking spherocytosis and microspherocytosis of the red cells, fewer than 20% being normal in appearance (Fig. 1).

FIG. 1.—Peripheral blood film on admission. (×610.)

Occasional Howell-Jolly bodies were present in red cells. No Gram-positive bacilli were seen. The whole blood clotting-time was 14 minutes. Clot retraction was normal. The plasma fibrinogen was 140 mg./100 ml. The level of factor VIII was 8% of normal. The patient's plasma had antithrombin activity when assayed by serial dilutions of thrombin, and prolonged the thrombin time of normal plasma, indicating the presence of a circulating anticoagulant. No increased fibrinolysis was observed in either whole blood clot or euglobulin clot within five hours, or on a fibrin plate within 18 hours. Plasminogen and activator were present in normal amounts as estimated by use of heated and unheated fibrin plates. Plasminogen was also normal when measured by casein lysis. Fibrin split products were detected in the serum both by immunodiffusion and by the haemagglutination inhibition assay (see Fig. 3). The plasma haemoglobin was 2,200 mg./100 ml. Serum electrolytes: sodium 124, potassium 6.4, chloride 89, and bicarbonate 13 mEq/L; blood urea 122 mg./100 ml.

FIG. 2.—Peripheral blood film 10 hours after exchange transfusion. ($\times 610$.)

Progress

Four hours after admission a Scribner shunt was placed between the right radial artery and vein and an exchange transfusion carried out. Nine litres of 18-hour-old bank blood was exchanged within 65 minutes; 2,000 units of heparin, 150 mg. of calcium chloride, and 100 mg. of hydrocortisone were added to each 500 ml. of blood. The central venous pressure and electrocardiogram remained within normal limits, and the blood pressure did not fall below 95/50 during the exchange transfusion.

There was marked improvement in the patient's condition; the mahogany discoloration of the skin was reduced and the nose and fingers became warmer. This was accompanied by a fall in plasma haemoglobin to 320 mg./100 ml., and a reduction in the level of fibrin split products (Fig. 3).

Next morning, 10 hours after the exchange transfusion, the peripheral blood film was nearly normal, with only occasional spherocytes (Fig. 2). The level of factor VIII had risen to 58% of normal, and the level of fibrinogen was 165 mg./100 ml.

Treatment was continued with heparin in a dose of 20,000 units subcutaneously every six hours, erythromycin 300 mg. intramuscularly every six hours, cephaloridine 1 g. intravenously every 12 hours, and gas-gangrene antitoxin 30,000 units intravenously every six hours. Oral fluid and dietary protein were restricted.

Fever subsided within 24 hours of admission. On Day 3 bleeding at injection sites and leakage of blood from the arteriovenous fistula occurred. This was attributed to heparin, and the morning dose was halved and the next dose omitted. Protamine sulphate 100 mg. was given at noon and a second dose of 85 mg. three hours later.

The following morning, 24 hours after stopping heparin and despite giving protamine, the bleeding tendency persisted. The level of fibrin split products had risen again (Fig. 3) and there was a slight fall in fibrinogen concentration. The whole blood clotting-time was 14 minutes and the prothrombin time 14 seconds.

Fibrinogen 7.5 g. was infused and heparin treatment restarted, 20,000 units being given daily by continuous intravenous infusion for the next 10 days. The bleeding lessened, and ceased within three days. The level of fibrin split products fell and the fibrinogen concentration and platelet count rose progressively, to reach peak values at 720 mg./100 ml. on the 10th day and greater than 700,000/cu. mm. on the 28th day respectively (Fig. 4). Haemoglobin levels remained normal and the white cell count returned to normal values within two weeks.

Complete anuria persisted during her first two weeks in hospital. The blood urea was maintained at approximately 100 mg./100 ml. by continuous peritoneal dialysis from Day 3 onwards. During the third week she began to pass small amounts of urine, which increased in volume over the next month to reach a daily output of 350 ml. The blood urea was kept at about 100 mg./100 ml. by peritoneal dialysis at night only.

During the seventh week of her admission she developed signs of consolidation of the lower lobe of the left lung. A heavy growth of *Pseudomonas pyocyanea* was cultured from the sputum. In spite of treatment with gentamicin 20 mg. intramuscularly eight-hourly her condition deteriorated and she died on the 48th day of her admission.

FIG. 3.—Effect of exchange transfusion and heparin treatment on level of plasma haemoglobin and fibrin split products ($\mu\text{g./ml.}$ of immunological reactive fibrinogen).

FIG. 4.—Level of plasma fibrinogen and of platelet count during patient's illness. The ^{131}I -fibrinogen and ^{51}Cr -platelet studies are indicated by heavy lines.

Post-mortem Examination

This was performed by the coroner's pathologist, Dr. D. A. Pocock, three days after death. There was a large purulent effusion in the left pleural cavity and pus could be expressed from the consolidated lower lobe of the left lung. There was no evidence of pulmonary infarction. The heart was normal except for minimal hypertrophy of the wall of the right ventricle. The peritoneal cavity showed no abnormality. The liver weighed 400 g. and on microscopical examination revealed fatty infiltration and occasional small areas of recent necrosis. The kidneys weighed 235 and 250 g. Microscopical examination showed severe tubular necrosis with numerous pigmented casts. The tubular epithelium showed signs of regeneration and there was no evidence of cortical necrosis. The uterus and adnexae were normal in size and appearance. Minimal signs of inflammation were found on microscopy. There was no evidence of thrombosis of the veins of the pelvis or lower limbs.

Special Haematological Studies

Fibrinogen Catabolism (Table and Fig. 5).—On Day 4 ^{125} I-labelled fibrinogen from a normal donor was injected. The level of radioactivity fell exponentially during the first four days, despite the rising level of plasma fibrinogen (Fig. 4). The catabolism of fibrinogen has been calculated between Day 8 and 12, when the plasma fibrinogen level was between 695 and 760 mg./100 ml. The half-life was 49.5 hours, and the fractional catabolic rate (the total amount of body fibrinogen catabolized daily expressed as a percentage of intravascular pool) was 46.8%. This represents a catabolic rate of 172 mg. of fibrinogen per kg. body weight per day. No significant amounts of radioactivity could be recovered in a trichloroacetic acid precipitate of peritoneal dialysate. A sample of the same batch of ^{125} I-fibrinogen injected into a normal control subject had a half-life of 114.5 hours and a normal catabolic rate. On Day 29 the ^{125} I-fibrinogen turnover was re-measured with the use of fibrinogen prepared from the patient's own plasma: the half-life was 65 hours and the fractional catabolic rate normal (27.3% per day).

Platelet Survival.—A survival study, using ^{51} Cr-labelled platelets obtained from a normal donor, was carried out on Day 13, when the platelet count was 165,000/cu. mm. All the radioactivity disappeared from the blood within one hour and none was detectable

FIG. 5.—Level of ^{125} I-fibrinogen in plasma during the two turnover studies.

^{125} I-fibrinogen Catabolism Calculated by the Method of Matthews (1957). For the First Study (Day 8–12) Fibrinogen was prepared from Plasma Obtained from the Control Subject. For the Second Study (Day 29–35) Fibrinogen was Prepared from Patient's Own Plasma

	Body Weight (Kg.)	Plasma Volume		Plasma Fibrinogen				Catabolic Rate		
				Pool		Half-life (Hr.)	I.V. fraction (%)	% / day	g. / day	mg. / kg. / day
		ml.	ml. / kg.	g.	mg. / kg.					
Patient { Day 8–12	57	3,170	55.6	22.6	396.5	49.5	78.5	46.8	9.8	172
Day 29–35	57	3,258	57.1	18.1	318	65	93.2	27.3	4.9	87
Control	70.6	2,693	38.2	6.6	93	114.5	87	17.0	1.1	16

in the circulation during the next four days. The survival re-estimated by using autologous platelets on Day 32, when patient's platelet count was 350,000/cu. mm. On this occasion mean platelet life-span was 134 hours (normal 192–240 hours).

Discussion

The patient had the classical features of severe clostridial septicaemia: anaemia, haemoglobinaemia, thrombocytopenia, generalized bleeding, and anuria (Isham and Finch, 1956; Muller, 1964; Decker and Hall, 1966).

Haemolytic Effect of Clostridial Alpha Toxin

The haemoglobinaemia was very severe and was associated with marked microspherocytosis of the red cells, probably due to the direct effect of the alpha toxin (lecithinase C) (Macfarlane *et al.*, 1941). Lecithinase C hydrolyses lecithin, a phospholipid component of the red cell membrane. The progressive loss of membrane phospholipid leads to the formation of spherocytes and microspherocytes (Jacob, 1966), possibly by a process of "fragmentation" (Weed and Reed, 1966). Such spherocytes are extremely sensitive to osmotic lysis. Loss of haemoglobin from red cells may also result from holes produced in the red cell membrane by some preparations of *Cl. perfringens* (Dourmashkin and Rosse, 1966). Lecithinase C also causes hydrolysis of platelet phospholipid, producing lysis, without aggregation, and the release of thromboplastin (platelet factor 3) and thrombocytopenia (Furr *et al.*, 1952). Intravascular coagulation will result from the release into the circulation of thromboplastins derived from both the platelets and the damaged red cells (Quick *et al.*, 1954; McKellar and Dacie, 1958; Bradlow, 1961; Rodriguez-Erdmann, 1965).

Evidence for Intravascular Coagulation

The low level of factor VIII and fibrinogen and the low platelet count present on admission indicated the consumption of coagulation factors. Further evidence of the occurrence of intravascular coagulation was the presence in the serum of fibrin split products, formed presumably as the result of fibrinolysis of microthrombi. These fibrin split products were probably also responsible for the antithrombin activity in the plasma (Fletcher *et al.*, 1962). The presence of fibrin split products implies activity of fibrinolysis, but the normal whole blood and euglobulin lysis times and the presence of normal levels of activator and plasminogen suggest that the fibrinolysis was restricted to sites where fibrin had been deposited in blood vessels (Pechet, 1965).

Yet further support for the continuance of a state of intravascular coagulation came from the findings of increased fibrinogen catabolism and shortened platelet life-span. The most striking finding in the ^{125} I-fibrinogen studies was the greatly increased fractional catabolic rate of 46.8% per day in the first study (Day 8–12). This contrasts with our finding of a fractional catabolic rate of $23 \pm 7\%$ per day in 10 control subjects (Baker *et al.*, 1967). In previous reports of fibrinogen catabolism in patients with elevated levels of fibrinogen and in normal control subjects the fractional catabolic rate has been found to be relatively constant, in keeping with the view that fibrinogen is catabolized as a first-order reaction, the amount

catabolized being directly proportional to the size of the fibrinogen pool (McFarlane *et al.*, 1964; Regöeczi *et al.*, 1964). Increases in fractional catabolic rate have been observed, however, in five other patients suspected of having intravascular coagulation (Baker *et al.*, 1967). In the second study (Day 29) an increase in the total amount of fibrinogen catabolized was associated with a normal fractional catabolic rate.

The first ^{51}Cr -platelet survival with use of normal donor platelets on Day 13, when the platelet count was 165,000/cu. mm., was highly unusual in that no circulating ^{51}Cr was detected one hour after injection. We believe this to be a valid observation, since the only previous occasion on which such a rapid rate of removal of platelets has been observed by us was in another patient with intravascular coagulation and only moderate thrombocytopenia (Brain *et al.*, 1967). The second platelet survival study on Day 32 with use of the patient's own platelets gave a nearly normal survival.

Effect of Exchange Transfusion and Heparin

The exchange transfusion resulted in a dramatic fall in the levels both of plasma haemoglobin and of fibrin split products; however, 10 hours later the levels of both had risen substantially. This might have been due to a redistribution of free haemoglobin and fibrin split products between the extravascular and intravascular compartments. Alternatively, the reabsorption into the circulation of tissue-bound alpha toxin might have continued to cause red cell damage despite treatment with antitoxin (Furr *et al.*, 1952). The rise in the level of fibrin split products might have been due to the continuing lysis of capillary microthrombi initially present or continuing to be formed.

A further rise in the level of fibrin split products, but not of plasma haemoglobin, occurred when heparin was stopped and protamine was given to neutralize the circulating heparin. These measures did not correct the bleeding state, and in fact resulted in a prolongation of the Quick one-stage prothrombin time and the whole blood clotting-time, and in the reappearance of a circulating antithrombin. These changes suggest that intravascular coagulation was accelerated when heparin was withdrawn. Reintroduction of heparin on Day 4 resulted in the complete disappearance of fibrin split products within 72 hours. A similar rise in the level of fibrin split products has been reported by Merskey *et al.* (1964), following the withdrawal of heparin given to a patient with disseminated intravascular coagulation. This observation, too, was interpreted as indicating a recurrence or continuance of intravascular coagulation.

The studies in this patient emphasize the importance of recognizing and treating the intravascular coagulation that may accompany clostridial septicaemia, a complication which would not be influenced by treatment with antibiotics and antitoxin. Though the continuing intravascular coagulation may be controlled with heparin, the presence of large numbers of damaged red cells, which would continue to undergo haemolysis and release thromboplastin, suggests that exchange transfusion may play an important part in the management of the initial stages of this serious condition.

Summary

A patient who had *Clostridium perfringens* (*Cl. welchii*) septicaemia following a self-induced abortion developed massive intravascular haemolysis, bleeding, and anuria. Approximately 80% of the red blood cells were spherocytes or microspherocytes. The finding of reduced levels of coagulation factors in the plasma, a low platelet count, and the detection of the products of fibrinolysis (fibrin split products) in the serum indicated the occurrence of disseminated intravascular coagulation. It was thought that this coagulation state

would be maintained by the continued release of thromboplastin from the toxin-damaged red cells.

The patient was therefore given an immediate exchange blood transfusion and heparin in addition to conventional management with antitoxin and antibiotics. The exchange transfusion was shown to remove spherocytic red blood cells, free haemoglobin, and fibrin split products from the circulation; it was followed by dramatic clinical improvement.

Subsequent measurements of serum level of fibrin split products, the turnover of ^{125}I -fibrinogen, and ^{51}Cr -platelet survival suggested that heparin therapy controlled but did not completely prevent the continuation of intravascular coagulation. These studies were repeated during the fourth week, three weeks after heparin had been stopped, and were now normal or nearly so.

The level of blood urea was controlled by peritoneal dialysis, and urine began to be passed in increasing amounts from the third week. The patient, however, developed pneumonia, and, despite treatment with antibiotics, died 48 days after admission.

Exchange transfusion and heparin may play an important part in the management of the initial stages of severe *Cl. perfringens* infections.

We are grateful to Dr. Oliver Wrong for allowing us to study the patient under his care, to Dr. Sheila Worledge for her assistance in obtaining the blood for the emergency exchange transfusion, and to Dr. D. A. Pocock for post-mortem specimens. We are indebted to Professor J. V. Dacie for help in the preparation of this paper, and to Misses Marion Scales and Gillian Bolton for their skilled assistance.

Comparison of Betamethasone 17-Valerate Ointment with Fluocortolone and Fluocortolone Caproate Ointment

DOWLING D. MUNRO,* M.B., M.R.C.P.; H. T. H. WILSON,† M.D., F.R.C.P.

ELLEN L. RHODES,‡ M.R.C.P., D.C.H.

Brit. med. J., 1967, 4, 275-276

Topical corticosteroids have revolutionized the therapy of many dermatoses. The value to the dermatologist of commercially available preparations reflects many factors, including the cost, potency, therapeutic efficiency, and cosmetic acceptability of the medicaments. Furthermore, since the pharmacology of most corticosteroids is similar, and the newer fluorinated compounds are of high potency, it becomes increasingly difficult for the clinician to assess the value of different preparations on the market.

Clinical impressions resulting from uncontrolled observations can be misleading, but properly conducted double-blind trials avoid the errors arising from bias on the part of the physician or patient. The present investigation compares the value of betamethasone 17-valerate ointment (Betnovate), with fluocortolone and fluocortolone caproate ointment (Ultralanum Plain). It is not intended as a comparison of the value of the constituent steroids or their bases, but as a clinical comparison of the two preparations as marketed in the United Kingdom.

Methods and Materials

Double-blind trial packs were prepared in pairs marked left and right. Betnovate ointment—that is, 0.1% betamethasone 17-valerate—and Ultralanum Plain ointment—that is, a mixture of 0.25% fluocortolone and 0.25% fluocortolone caproate—were randomly allocated to the left and right sides: each tube contained 30 g. of the relevant ointment. Each paired pack was numbered and the code given to the clinicians in sealed envelopes, which remained closed throughout the trial.

Three dermatologists from different centres co-operated in the trial. The same dermatologist saw the patient before and after treatment, and recorded details of the cases on a standard form.

Individuals admitted to the trial were suffering from either eczema or psoriasis and were treated as outpatients. Only those having approximately symmetrical involvement of right and left sides were studied, and there was random selection in so far as all suitable patients referred to the clinics were consecutively included in the trial. Patients were instructed to apply the test ointments twice daily; some, where it was felt to be necessary, were told to occlude affected areas with polyethylene film. Mild sedatives or antihistamines were administered if indicated.

Detailed records of individual patients included name, age, sex, diagnosis, and sites and extent of the disease, together with the history and duration of previous therapy. In the trial the dermatologist's assessment ("objective") and the patient's views ("subjective") of the relative improvement between sides were compared and separately recorded as "healed," "improved,"

"static," or "worse." The dermatologist assessed improvement by observing reduction in erythema, scaling, induration, and oedema of the diseased skin. The patient assessed the changes in itching or other symptoms. The two sides were simply compared, no attempt at quantitative assessment being made. The patients were normally reviewed after seven days, though some were seen more frequently, and a few at slightly longer intervals.

When the investigation on each patient was concluded, the completed form was returned to a co-ordinating secretary, who decoded the results and plotted them consecutively on previously constructed restricted sequential analysis graphs (Armitage, 1960) having a design designated by the factors

$$2\alpha = 0.05, 1 - \beta = 0.95, \theta_1 = 0.85.$$

A total of 109 patients were included in the trial. Of these, 66 had eczema and 43 had psoriasis. Their ages ranged from 6 months to 76 years and the sex ratio was 48 males to 61 females. These two groups were subdivided into those occluded with polyethylene, and those treated without polyethylene. Two patients who were initially included in the trial failed to carry out the instructions given by the clinicians and were therefore excluded from the investigation.

The total numbers treated are shown in the Table. Statistical investigations, by means of restricted sequential analysis, of the results in the first two groups are shown in Fig. 1 (eczema) and Fig. 2 (psoriasis). This method of statistical evaluation excludes patients in whom both sides responded equally ("tied pairs"), but these are shown in the Table.

Comparison of Betamethasone 17-Valerate Ointment with Fluocortolone Caproate Ointment in Treatment of 66 Patients with Eczema and 43 Patients with Psoriasis

	Eczema				Psoriasis			
	Non-occl.		Occluded		Non-occl.		Occluded	
	Phys	Pat	Phys	Pat	Phys	Pat	Phys	Pat
Betamethasone 17-val. superior ..	23	21	14	14	11	10	14	15
Fluocortolone comp. superior ..	5	5	10	7	3	4	3	3
Equally good ..	9	11	5	8	9	9	3	2

Phys = Physician's opinion. Pat = Patient's opinion.

In the eczema group (Table and Fig. 1) betamethasone 17-valerate was shown to be statistically superior at the 5% level in patients treated without occlusion, and the boundary was reached after 30 patients. In patients treated with plastic occlusive dressings the "no significant difference" boundary was reached after 25 patients had been investigated.

In the psoriasis group (Table and Fig. 2) patients treated either with or without polyethylene occlusion responded better to betamethasone 17-valerate ointment than to the fluocortolone compound ointment. The statistically significant boundary at the 5% level was reached after 20 cases were treated with occlusion and 17 cases without occlusion.

The patient's own opinions, also included in the Table, show a remarkable correlation between them and their physicians in

the assessment of response. On the whole, when they differed in their views on which side was most improved, the variation between sides was slight.

Discussion

Under the conditions of the trial betamethasone 17-valerate ointment was impressively better than the fluocortolone preparation in the treatment of psoriasis, whether occluded or not, and in eczema when used without occlusion. In other independent trials—mainly psoriasis treated with occlusion—fluocortolone alone, and also with fluocortolone caproate and clemizole-hexachlorophane, has similarly been shown to be less effective than betamethasone 17-valerate (Sneddon, 1966, 1967). The use of occlusive dressings increases humidity and the temperature of the skin, resulting in increased percutaneous absorption. This tends to mask differences in efficiency of steroid

were not too subtle for the patients to be conscious of them. A multicentred trial such as the present one has the advantage that minor centre-by-centre differences in the objective assessments tend to be corrected. In one centre, investigation of the eczema non-occluded group of cases was continued after the main trial was completed, and showed a similar pattern of significance for betamethasone 17-valerate ointment after 20 cases had been studied.

There are difficulties in assessing statistically the biological response to two drugs, and sequential analysis has disadvantages if the number of "tied pairs" of equal response is large. Variation in the pattern of the graph can occur, depending on the order in which results are plotted. In this investigation the results were plotted strictly according to the date of reaching a conclusion for a particular patient in the trial. If two cases were completed on the same date, then the lower number of the paired packs was plotted first. The advantages of sequential

analysis are that, by prior determination of the limits of the trial, a statistically acceptable assessment is achieved with the minimum number of patients, and that such data can be easily presented.

It should be emphasized that this trial does not compare the active constituents of the two ointments but was specifically designed to compare two commercially available products. The total strengths of the steroid constituents differed as did the bases, the betamethasone 17-valerate preparation being in a soft paraffin and hydrogenated lanolin base, while the fluocortolone preparation was in a soft paraffin aqueous emulsion containing 30% water. One preparation (betamethasone 17-valerate ointment), was superior to the other (fluocortolone

preparations of different potency (Thomsen, 1966), and was demonstrated in the present trial by the group of patients suffering from eczema and treated with occlusion, in whom the two preparations gave a similar response. Topical corticosteroids when applied in large amounts under occlusive dressings may depress the hypothalamic-pituitary-adrenal axis (Scoggins, 1962; Strange and Hjorth, 1965; Munro *et al.*, 1967). In small quantities, such as were used in this investigation, systemic effects would be minimal.

Psoriasis is more resistant than eczema to treatment with corticosteroids, and even hydrocortisone, which gives little benefit in psoriasis, usually produces considerable improvement in eczema. It would appear, therefore, that response in psoriasis is a more stringent test of the efficacy of a corticosteroid than response in eczema. The superiority of betamethasone 17-valerate ointment in this context is noteworthy. The mechanism of action of corticosteroids on psoriasis is unknown but probably relates to the prolongation of epidermal cell turnover times which has been shown to occur in normal skin treated with a corticosteroid (Munro, 1967). However, from a clinical viewpoint corticosteroids, while useful in some psoriatic cases, are not the treatment of choice in many cases owing to their tendency to relapse when therapy is discontinued—presumably as the result of epidermal cell proliferation returning to the psoriatic pattern.

Differences in the response to the two preparations were slight in many patients, and it had been noted previously that experienced observers tended to record differences which were not obvious to clinicians less accustomed to observing dermatological disease. However, the correlation between objective and subjective findings was good, thus emphasizing that differences

caproate ointment) in three out of the four groups studied, but this does not mean there is no place in the market for the compound that appeared in this short-term trial to be less effective. Individuals respond differently, and some steroid compounds seem to become less effective as treatment continues. The dermatologist is often looking for different potent compounds to use while the natural tendency for the skin to heal is occurring. Both the ointments tested contain powerful corticosteroids and, as such, have their use.

Summary
